Brief Content

Volume I

Acceptance Sampling.....	1	Biologics	233
Active Control Non-Inferiority Trials: Hypotheses and False Positive Rate.....	8	Biomarker Development with Applications to Genetics Data: Statistical Tests.....	243
Active Control Trials.....	14	Biomarker: Clinical Trials	251
Active Controlled Clinical Trials: Noninferiority Analysis	23	Biopharmaceutics.....	254
Adaptive Design Clinical Trials: Case Studies.....	28	Biosimilar Studies: Sample Size.....	274
Adaptive Design Methods in Clinical Trials	36	Biosimilar Studies: Three-Arm Design.....	277
Adaptive Survival Trials.....	50	Biosimilarity Assessment	281
Adverse Event Reporting.....	53	Biosimilarity of Follow-On Biologics.....	304
Alpha Spending Function	59	Bivariate Zero-Inflated Poisson Populations: Statistical Test for Homogeneity	316
Ames Test	67	Blinded Sample Size Re-Estimation.....	323
Analysis of $2 \times K$ Tables	75	Blinding.....	336
Analysis of Clustered Binary Data.....	82	Bootstrap, The	342
Analysis of Clustered Categorical Data.....	88	Botanical Drug Product Development: Scientific Issues	348
Analysis of Heritability	98	Bracketing Design	359
Analysis of Variance (ANOVA).....	104	Bridging Studies.....	361
Analytical Similarity Assessment.....	116	Bridging Studies: Statistical Methods.....	366
ANCOVA Approach: Premarketing Shelf Life Determination with Multiple Factors	125	Calibration	370
Assay Development	130	Canadian Health Products and Food Branch (HPFB) and Therapeutic Products Directorate (TPD).....	378
Assay Validation.....	138	Cancer Chemotherapy: Maximum Tolerable Dose	384
Assay Validation: Evaluation of Linearity	146	Cancer Trials	390
Bayesian Designs: Phase II Oncology Clinical Trials	154	Carcinogenicity Studies of Pharmaceuticals	398
Bayesian Estimate: Concordance Correlation Coefficient.....	164	Carry-Forward Analysis.....	416
Bayesian Methods: Meta-Analysis.....	173	Case-Control Studies: Inference in	422
Bayesian Methods: Stability Analysis	180	Center Weighting: Multicenter Trials.....	435
Bayesian Model: Prior Effective Sample Size	186	Clinical Data Management.....	444
Bayesian Statistics	190	Clinical Endpoint.....	451
Bayesian Statistics: Medical Device Clinical Trials	198	Clinical Endpoint BE Studies: Generic Drugs	455
Binary 2×2 Crossover Trials	206	Clinical Inspection: Statistical Process.....	462
Bioassay.....	213	Clinical Pharmacology	469
Bioavailability and Bioequivalence.....	216	Clinical Research: Benefit and Risk Assessment.....	472
Bioinformatics	224	Clinical Research: Comparing Variabilities	486
		Clinical Research: Outlier Detection.....	502
		Clinical Research: Reproducibility Probability	510

Volume I (cont'd.)

Clinical Trial Design: Statistical Assurance.....	523
Clinical Trial Designs with Prospective Patient Population Enrichment by Response.....	526
Clinical Trial Process.....	532
Clinical Trial Simulation.....	536
Clinical Trial Simulations: Earlier Development Phases.....	539
Clinical Trial Simulations: Later Development Phases.....	544
Clinical Trial: Combination Drug Development.....	552
Clinical Trial: Failure-Time Model.....	556
Clinical Trial: <i>N</i> -of-1 Design Analysis.....	564
Clinical Trials.....	572
Clinical Trials: Controversial Issues.....	580

Volume II

Clinical Trials: Interval-censored Failure Time Data.....	589
Clinical Trials: Investigating Quality-of-Life.....	597
Clinical Trials: Meta-Analysis using R.....	603
Clinical Trials: Response-Adaptive Repeated Measurement Designs.....	612
Clinical Trials: Selection of Control.....	622
Clinical Trials: Vaccine Development.....	628
Cluster Randomized Trials: Sample Size.....	645
Cluster Trials.....	648
Clustered Study Designs: Power Analysis.....	658
Companion Diagnostics.....	672
Comparability Studies: Statistical Considerations.....	682
Confidence Interval and Hypothesis Testing.....	699
Confounding and Interaction.....	703
Content Uniformity.....	709
Continual Reassessment Methods.....	712
Contract Research Organization (CRO): Early 2000s.....	716
Contract Research Organization (CRO).....	721
Controlled Clinical Trials: <i>P</i> -Values, Evidence, and Multiplicity Considerations.....	725
Correlated Probit Model.....	741

Cost-Effectiveness Analysis.....	751
Covariate-Adjusted Adaptive Dose-Finding: Early Phase Clinical Trials.....	760
Covariates: Adjustment for.....	772
Crossover Design.....	776
Crossover Design: Rank-Based Robust Analysis.....	784
Cutoff Designs.....	798
Data Mining and Biopharmaceutical Research.....	805
Data Monitoring Committees (DMC).....	811
Diagnostic Device Evaluation.....	822
Diagnostic Imaging.....	829
Diagnostic Procedure: Sensitivity and Specificity.....	836
Disease Modification Effects: Design and Analysis.....	839
Dissolution Profile Comparison: Statistical Methods.....	844
Dissolution Profiles Comparison: Model-Independent Approaches.....	854
Dosage Units Using Small and Large Sample Sizes: Uniformity.....	859
Dose Finding Clinical Trials Using R.....	866
Dose Proportionality.....	876
Dose Response Analysis in Clinical Trials.....	879
Dose Response Study Design.....	885
Dose-Ranging Studies: Design Considerations.....	891
Dropout.....	901
Drug Development.....	908
Drug Interchangeability: Biosimilar Products.....	914
Drug Interchangeability: Criteria and Design.....	922
Drug Interchangeability: Meta-Analysis for Safety Monitoring.....	928
Drug Interchangeability: Generic Products, Prescribability and Switchability.....	935
Ecologic Inference.....	940
ED ₅₀ /ED ₉₀	952
Enrichment Design.....	960
Enrichment Design with Patient Population Augmentation.....	964
Equivalence Trials.....	970
Ethnic Factors.....	976
Expiration Dating Period.....	979

Exploratory Factor Analysis.....	985	Kruskal-Wallis Test for Ordered	
Extra Variation Models.....	992	Categorical Data: Power Calculation	1245
Factor Analysis.....	1008	Kullback–Leibler Divergence for	
Factorial Designs	1014	Evaluating Equivalence	1249
False Discovery Rate (FDR)	1028	Laboratory Analyses	1258
GEE in Cancer Research	1036	Latent Class Analysis.....	1266
Generalizability Probability in		Lilly Reference Ranges	1276
Clinical Research	1042	Local Influence Analysis	1292
Generalized Estimating Equation	1046	LOCF: Validity	1296
Generalized Inference	1054	Logistic Regression	1303
Genetic Linkage and Linkage		Logistic Regression Process: Predictive	
Disequilibrium Analysis	1057	Model Building in Clinical Research	1309
Global Database and System	1069	Logistic Regression: Three-Point	
Good Clinical Practice (GCP)	1075	Designs	1315
Good Laboratory Practice (GLP)	1082	McNemar’s Test.....	1320
Good Programming Practice (GPP)	1088	MCP-Mod: Dose–Response Testing	
Good Statistics Practice (GSP).....	1095	and Estimation	1326
Good Validation Practice (GVP)	1101	Measuring Agreement.....	1335
Group Sequential Methods	1105	MedDRA: Impact on Pharmaceutical	
Group Sequential Tests and Variance		Development.....	1342
Heterogeneity: Clinical Trials	1114	Medical Devices	1348
Human Drug Abuse Trials	1121	Meta-Analysis of Therapeutic Trials.....	1362
Hypothesis Testing.....	1124	Microarray Gene Expression	1377
Imputation with Item Nonrespondents	1128	Microdosing Studies	1394
Imputation: Clinical Research	1135	Minimization Procedure.....	1401
<i>In Vitro</i> Testing: Bioequivalence	1141	Minimum Effective Dose.....	1406
<i>In Vitro</i> Testing: Dissolution Profile		Mixed Effects Models	1409
Comparison	1148	Mixed-Outcome Data	1414
<i>In Vitro</i> Testing: Micronucleus Test.....	1155	MMRM with Missing Data.....	1422
Individual Bioequivalence.....	1160	Modified Large Sample Method.....	1427
		Multicenter Trials	1434
		Multicollinearity	1438
		Multidimensional Data Analysis:	
		Penalized Regression Methods	1448
		Multinational Clinical Trials	1454
		Multiple Comparisons.....	1461
		Multiple Endpoints	1467
		Multiple-Dose Bioequivalence Studies.....	1477
		Multiple-Stage Designs: Phase II	
		Cancer Trials.....	1481
		Multiplicative Intensity Models	1494
		Multiplicity in Clinical Trials.....	1502
		Multi-Regional Clinical Trials:	
		Consistency Test	1511
		Multiregional Clinical Trials: Qualitative	
		Consistency of Treatment Effects	1522
		Multivariate Meta-Analysis	1528
		Noninferiority Trials: Type I Error Rates.....	1536
		Nonparametric Regression	1543

Volume III

Instrument Development and	
Validation.....	1167
Integrated Summary Report	1179
Intention-to-Treat Analyses (ITT).....	1183
Interchangeability: Generic Drugs	1187
Interim Analysis.....	1195
International Conference on	
Harmonization (ICH).....	1202
Item Response Theory.....	1207
IVRS/IWRS for Randomization	1216
Japan: Ministry of Health, Labour and	
Welfare and Pharmaceutical	
Administration	1224
Kaplan–Meier Estimator	1231
Kappa Coefficients: Medical Research	1237

Volume III (cont'd.)

Odds Ratio	1554	Propensity Score Analysis and Its Application in Regulatory Settings	1823
Oncology Clinical Trials: Efficient Dose-Finding Designs	1560	Propensity Score: Methodology and Application to Clinical Studies	1825
Oncology Trials: Development Strategy	1572	Proportion of Treatment Effect	1830
Onset of Action	1585	Proportional Hazards Regression Model	1834
Optimal Futility Interim Design	1593	Protocol Development	1841
Ordered Categorical Data: Test for	1602	P-Values	1845
Ordered Multiple Class Receiver Operating Characteristic (ROC) Analysis	1608	QT Analysis	1855
Ordinal Data: Crossover Design Analysis	1613	Quality by Design in Biopharmaceutical Development	1865
Parallel Design	1621	Randomization	1875
Patient Compliance	1627	Randomized Trials with Clusters: Design and Analysis	1880
Patient-Reported Outcomes	1633	Rank Regression: Stability Analysis	1888
Percentile Charts on Correlated Measures	1643	Regulatory Statistics	1893
Personalized Medicine: Validation of Diagnostic Medical Devices	1648	Release Targets	1903
Pharmaceutical Development: Statistical Designs	1656	Reliability	1908
Pharmacodynamic Issues	1665	Repeated Measurement Designs: Missing Values	1918
Pharmacodynamics with Covariates	1673	Repeated Measures Data with Missing Values Analysis: Overview of Methods	1924
Pharmacodynamics with No Covariates	1685	Reproductive and Developmental Studies	1931
Pharmacoeconomics	1693	Response Surface Methodology	1939
Pharmacoeconomics: Cost-Effectiveness Analysis	1707	Response-Adaptive Designs	1950
Phase I Cancer Clinical Trials	1715	Risk Ratio Analysis	1956
Phase II Clinical Development	1721	ROC Curve	1962
Phase III Clinical Trials with Response- Adaptive Allocation	1727	Sample Size Calculation: Nonparametrics	1970
Placebo Effect	1735	Sample Size Calculation: Survival Data	1980
Population Bioequivalence	1740	Sample Size Determination	1987

Volume IV

Population PK/PD Analysis	1747	Sample Size Determination: Three-arm Ratio of Mean Differences Equivalence Test	2002
Postmarketing Adverse Drug Event Signaling	1756	Sample Size Estimation: Generalized Estimating Equations (GEE) Method	2010
Postmarketing Surveillance	1769	Sample Size for Multiregional Clinical Trials	2015
Power	1777	Sample Size Re-estimation Based on Observed Treatment Difference	2021
Precision Medicine: Statistical Issues	1779	Sample Size Re-estimation Design with Robust Power	2026
Prediction Trees	1782	Sample Size: Negative Binomial With Unequal Follow-Up Times	2031
Premarket Applications: Registries	1791	Scaled Average Bioequivalence (SABE)	2038
Principal Component Analysis	1796	Screening Design	2045
Process Validation	1802	Seamless Adaptive Trial Design: Dose Selection Criteria	2047
Profile Analysis	1817		

Semi-Parametric Time-Varying		
Regression Models.	2058	
Sequential Estimation: Additive Hazards		
Rate Model with Staggered Entry.	2063	
Signal Detection in Pharmacovigilance.	2068	
Slope Approach: Assessment of Dose		
Proportionality and Linearity Under a		
Crossover Design.	2084	
Spatio-Temporal Modeling.	2089	
Specifications.	2099	
SROC Curve.	2101	
Stability Analysis: Frozen Drug		
Products.	2111	
Stability Matrix Designs.	2116	
Statistical Genetics.	2122	
Statistical Principles for Clinical Trials.	2130	
Statistical Process Control.	2135	
Statistical Significance.	2142	
Structural Equation Model.	2147	
Stuart–Maxwell Test.	2154	
Subgroup Analysis.	2159	
Subject-Treatment Interaction.	2167	
Surrogate Endpoint.	2174	
Survival Analysis.	2179	
Targeted Clinical Trials.	2184	
Testing for Qualitative Interaction.	2192	
Therapeutic Equivalence.	2199	
Thorough QT Studies.	2206	
Tiered Approach of Analytical Similarity		
Assessment: Statistical Methods.	2219	
Titration Design.	2225	
Toxicological Studies.	2230	
Traditional Chinese Medicine (TCM):		
Clinical Development.	2244	
Traditional Chinese Medicine (TCM):		
General Considerations.	2252	
Traditional Chinese Medicine (TCM):		
Unified Approach for Evaluation.	2265	
Translational Medicine: Concepts, Statistical		
Methods, and Related Issues.	2270	
Trend Estimation.	2283	
Two-Stage Adaptive Design: Analysis.	2289	
Two-Stage Design: Phase II Cancer		
Clinical Trials.	2296	
US Food and Drug Administration.	2305	
USP Tests.	2311	
Validation of Quantitative and		
Qualitative Assays.	2313	
Weibull Model: Group Sequential Design.	2325	
Z-Score.	2329

- Zhongwen Tang** / *Novartis, East Hanover, New Jersey, U.S.A.*
- Zhaoyang Teng** / *Takeda Pharmaceuticals Inc., Cambridge, Massachusetts, U.S.A.*
- Peter F. Thall** / *Department of Biostatistics, The University of Texas, M.D. Anderson Cancer Center, Houston, Texas, U.S.A.*

- Laura Thompson** / *Division of Biostatistics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Naitee Ting** / *Department of Biostatistics and Data Sciences, Boehringer-Ingelheim Pharmaceuticals, Inc., Ridgefield, Connecticut, U.S.A.*
- J. Tiwari** / *U.S. Food and Drug Administration, Rockville, Maryland, U.S.A.*
- Laszlo Tothfalusi** / *Department of Pharmacodynamics, Semmelweis University, Budapest, Hungary*
- William M. K. Trochim** / *Department of Policy Analysis and Management, Cornell University, Ithaca, New York, U.S.A.*
- Siu-Keung Tse** / *Department of Management Sciences, City University of Hong Kong, Hong Kong, China*
- Yi Tsong** / *Office of Biostatistics, Office of Translational Sciences, CDER, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Hsiao-Hui Tsou** / *Institute of Population Health Sciences, National Health Research Institutes, Miaoli, Taiwan*
- Dongsheng Tu** / *NCIC Clinical Trials Group, Queen's University, Kingston, Ontario, Canada*
- X. M. Tu** / *Department of Biostatistics and Computational Biology, University of Rochester, Rochester, New York, U.S.A.*
- Merlin L. Utter** / *Pfizer Inc., Pearl River, New York, U.S.A.*
- Mårten Vågerö** / *AstraZeneca R&D Södertälje, Södertälje, Sweden*
- K. Van Steen** / *Montefiore Institute – Systems and Modeling Unit; Bioinformatics and Modeling, Université de Liège, Liège; and Department of Human Genetics, Catholic University of Leuven, Leuven, Belgium*
- Julia A. Varshavsky** / *Eli Lilly and Company, Indianapolis, Indiana, U.S.A.*
- R. Lakshmi Vishnuvajjala** / *Division of Biostatistics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- S. D. Walter** / *Department of Clinical Epidemiology and Biostatistics, Faculty of Health Sciences, McMaster University, Hamilton, Ontario, Canada*
- Hansheng Wang** / *Peking University, Beijing, People's Republic of China*
- Hongwei Wang** / *Merck & Co., Inc., Rahway, New Jersey, U.S.A.*
- Kongming Wang** / *Department of Statistics, Pfizer Inc., New York, New York, U.S.A.*
- Sue-Jane Wang** / *Office of Biostatistics, Office of Translational Sciences, Center for Drug Evaluation and Research, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- William W. B. Wang** / *Merck Research Laboratories, West Point, Pennsylvania, U.S.A.*
- Xiaoming Wang** / *Shanghai University of Finance and Economics, Shanghai, China*
- Yong-Cheng Wang** / *Division of Biometrics I, Office of Biostatistics, Office of Pharmacoeconomics and Statistical Science, Center for Drug Evaluation and Research, U.S. Food and Drug Administration, Rockville, Maryland, U.S.A.*
- Greg C. G. Wei** / *Pfizer Global Research and Development, Groton, Connecticut, U.S.A.*
- Thomas R. Weihrauch** / *Bayer AG, Wuppertal, Germany*
- Peter Westfall** / *Area of Information Systems and Quantitative Sciences, Texas Tech University, Lubbock, Texas, U.S.A.*
- Michael G. Wilson** / *Butler University, Indianapolis, Indiana, U.S.A.*
- Robert L. Wong** / *Abbott Laboratories, Parsippany, New Jersey, U.S.A.*
- Jiang-Ming Johnny Wu** / *Biostatistics, DOV Pharmaceutical, Inc., Somerset, New Jersey, U.S.A.*

- Jianrong Wu** / *Department of Biostatistics, St. Jude Children's Research Hospital, Memphis, Tennessee, U.S.A.*
- Jincao Wu** / *Division of Biostatistics, Office of Surveillance and Biometrics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Rongling Wu** / *Departments of Public Health Science and Departments of Statistics, Pennsylvania State University, University Park, Pennsylvania, U.S.A.*
- Chien-Hua Wu** / *Department of Applied Mathematics, Chung-Yuan Christian University, Chung-Li, Taiwan*
- Yuh-Jenn Wu** / *Department of Applied Mathematics, Chung Yuan Christian University, Taoyuan, Taiwan*
- Liming Xiang** / *Nanyang Technology University, Singapore*
- Yaji Xu** / *Division of Biostatistics, Office of Surveillance and Biometrics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Yunling Xu** / *Division of Biostatistics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Zhiheng Xu** / *Division of Biostatistics, Office of Surveillance and Biometrics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Aileen L. Yam** / *Independent Consultant*
- Xin Yan** / *Merck Research Laboratories, Blue Bell, Pennsylvania, U.S.A.*
- Xu Yan** / *Division of Biostatistics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Bo Yang** / *Biometrics, Vertex Pharmaceuticals, Boston, Massachusetts, U.S.A.*
- Chunyan Yang** / *Hong Kong Baptist University, Hong Kong; and Yunnan University, Kunming, Yunnan, China*
- Jing Yang** / *Gilead Sciences, Foster City, California, U.S.A.*
- Harry Yang** / *MedImmune, LLC, Gaithersburg, Maryland, U.S.A.*
- Jingjing Ye** / *Division of Biometrics V, Office of Biostatistics, Center for Drug Evaluation and Research, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Laura Yee** / *Division of Biostatistics, Office of Surveillance and Biometrics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Constantin T. Yiannoutsos** / *Division of Biostatistics, Indiana University School of Medicine, Indianapolis, Indiana, U.S.A.*
- Lisa Ying** / *Bristol-Myers Squibb Company, Princeton, New Jersey, U.S.A.*
- Gloria H. Yiu** / *The Procter & Gamble Co., Cincinnati, Ohio, U.S.A.*
- Tinghui Yu** / *Division of Biostatistics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Guojun Yuan** / *LFB USA, Inc., Framingham, Massachusetts, U.S.A.*
- Mengdie Yuan** / *Center for Drug Evaluation and Research, Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Lilly Q. Yue** / *Division of Biostatistics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Hak-Keung Yuen** / *Department of Management Sciences, City University of Hong Kong, Hong Kong, China*

- Langche Zeng** / *Department of Political Science, University of California, San Diego, California, U.S.A.*
- Na Zeng** / *National Clinical Research Center for Digestive Disease, Beijing Friendship Hospital, Capital Medical University, Beijing, China*
- Donghui Zhang** / *Department of Biostatistics and Programming, Sanofi US Inc., Bridgewater, New Jersey, U.S.A.*
- J. Zhang** / *Department of Biostatistics, Harvard School of Public Health, Boston, Massachusetts, U.S.A.*
- Lanju Zhang** / *Data and Statistical Science, AbbVie Inc., North Chicago, Illinois, U.S.A.*
- Shu Zhang** / *Sepracor, Inc., Marlborough, Massachusetts, U.S.A.*
- Ying Zhang** / *AIG American General, Neptune, New Jersey, U.S.A.*
- Zhiwei Zhang** / *Department of Statistics, University of California, Riverside, Riverside, California, U.S.A.*
- Joanne Zhang** / *Office of Biostatistics, Office of Translational Sciences, CDER, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Lanju Zhang** / *Data and Statistical Sciences, AbbVie Inc., North Chicago, Illinois, U.S.A.*
- Jun Zhao** / *Merck Research Laboratories, Summit, New Jersey, U.S.A.*
- Zhigen Zhao** / *Department of Statistics, Temple University, Philadelphia, Pennsylvania, U.S.A.*
- Gang Zheng** / *National Heart, Lung and Blood Institute, Bethesda, Maryland, U.S.A.*
- Jiayin Zheng** / *Department of Biostatistics and Bioinformatics, Duke University School of Medicine, Durham, North Carolina, U.S.A.*
- Yanbing Zheng** / *Data and Statistical Sciences, AbbVie Inc., North Chicago, Illinois, U.S.A.*
- Bob Zhong** / *Janssen Pharmaceutical Companies, Johnson and Johnson, Malvern, Pennsylvania, U.S.A.*
- Jinglin Zhong** / *Division of Biometrics IV, Center for Drug Evaluation and Research, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.*
- Jihao Zhou** / *Department of Biostatistics, Allergan, Inc., Irvine, California, U.S.A.*
- Qingning Zhou** / *University of Missouri, Columbia, Missouri, U.S.A.*
- Yijie Zhou** / *Data and Statistical Science, AbbVie Inc., North Chicago, Illinois, U.S.A.*
- Li Zhu** / *Amgen Inc., Thousand Oaks, California, U.S.A.*

Contents

<i>Contributors</i>	xiii
<i>Topical Table of Contents</i>	xxxv
<i>Preface</i>	xlvi
<i>About the Editor-in-Chief</i>	xlix

Volume I

Acceptance Sampling / William A. Brenneman and William R. Myers	1
Active Control Non-Inferiority Trials: Hypotheses and False Positive Rate / Gang Chen, George Y. H. Chi, and Yong-Cheng Wang	8
Active Control Trials / George Y. H. Chi, Gang Chen, Mark Rothmann, and Ning Li	14
Active Controlled Clinical Trials: Noninferiority Analysis / Sue-Jane Wang, H. M. James Hung, and Yi Tsong	23
Adaptive Design Clinical Trials: Case Studies / Shiohjen Lee and Min Lin	28
Adaptive Design Methods in Clinical Trials / Shein-Chung Chow and Annpey Pong	36
Adaptive Survival Trials / William F. Rosenberger and Lanju Zhang	50
Adverse Event Reporting / Cynthia Pennise	53
Alpha Spending Function / Jihao Zhou and Glen Andrews	59
Ames Test / Wherly P. Hoffman and Michael L. Garriott	67
Analysis of $2 \times K$ Tables / Shiva Gautam	75
Analysis of Clustered Binary Data / Valerie Durkalski	82
Analysis of Clustered Categorical Data / Kalyan Das	88
Analysis of Heritability / Brent D. Burch and Ian R. Harris	98
Analysis of Variance (ANOVA) / Maria Overbeck-Larisch and Werner Sanns	104
Analytical Similarity Assessment / Shein-Chung Chow, Fuyu Song, and He Bai	116
ANCOVA Approach: Premarketing Shelf Life Determination with Multiple Factors / Yi Tsong, Chi-wan Chen, Wen Jen Chen, Roswitha E. Kelly, Daphne T. Lin, and Karl K. Lin	125
Assay Development / Timothy L. Schofield	130
Assay Validation / Timothy L. Schofield	138
Assay Validation: Evaluation of Linearity / Jen-pei Liu and Eric Hsieh	146
Bayesian Designs: Phase II Oncology Clinical Trials / Sze Huey Tan, David Machin, and Say Beng Tan	154
Bayesian Estimate: Concordance Correlation Coefficient / Dai Feng, Richard Baumgartner, and Vladimir Svetnik	164
Bayesian Methods: Meta-Analysis / Elizabeth Stojanovski and Kerrie L. Mengersen	173
Bayesian Methods: Stability Analysis / Jie Chen, Jinglin Zhong, and Lei Nie	180
Bayesian Model: Prior Effective Sample Size / Satoshi Morita and Peter F. Thall	186
Bayesian Statistics / Julia A. Varshavsky and Stacy R. Lindborg	190
Bayesian Statistics: Medical Device Clinical Trials / Gerry W. Gray, Xuefeng Li, Laura Thompson, Yunling Xu, Xu Yan, and Lilly Q. Yue	198
Binary 2×2 Crossover Trials / Li Zhu, Juan Li, and Eric Chi	206
Bioassay / Anant M. Kshirsagar	213
Bioavailability and Bioequivalence / Mengdie Yuan and Jingyu Julia Luan	216
Bioinformatics / Sean D. Mooney and Jeffrey T. Chang	224

Volume I (cont'd.)

Biologics / P. A. Lachenbruch, A. D. Horne, C. J. Lynch, J. Tiwari, and Susan S. Ellenberg	233
Biomarker Development with Applications to Genetics Data: Statistical Tests / Gang Zheng and Jungnam Joo	243
Biomarker: Clinical Trials / Mark Chang	251
Biopharmaceutics / Iain J. McGilveray	254
Biosimilar Studies: Sample Size / Seung-Ho Kang	274
Biosimilar Studies: Three-Arm Design / Seung-Ho Kang	277
Biosimilarity Assessment / Shein-Chung Chow and Fuyu Song	281
Biosimilarity of Follow-On Biologics / Shein-Chung Chow and Jen-pei Liu	304
Bivariate Zero-Inflated Poisson Populations: Statistical Test for Homogeneity / Siu-Keung Tse and Hak-Keung Yuen	316
Blinded Sample Size Re-Estimation / Chien-Hua Wu	323
Blinding / Shein-Chung Chow and Jun Shao	336
Bootstrap, The / Shein-Chung Chow and Jun Shao	342
Botanical Drug Product Development: Scientific Issues / Annpey Pong and Shein-Chung Chow	348
Bracketing Design / John R. Murphy	359
Bridging Studies / Jen-pei Liu	361
Bridging Studies: Statistical Methods / Yuh-Jenn Wu, Chieh Chiang, Chi-Tian Chen, Hsiao-Hui Tsou, and Chin-Fu Hsiao	366
Calibration / Shein-Chung Chow	370
Canadian Health Products and Food Branch (HPFB) and Therapeutic Products Directorate (TPD) / Dongsheng Tu	378
Cancer Chemotherapy: Maximum Tolerable Dose / Jen-pei Liu	384
Cancer Trials / Clet Niyikiza and Douglas E. Faries	390
Carcinogenicity Studies of Pharmaceuticals / Karl K. Lin	398
Carry-Forward Analysis / Naitee Ting	416
Case-Control Studies: Inference in / Gary King and Langche Zeng	422
Center Weighting: Multicenter Trials / Paul Gallo	435
Clinical Data Management / Terri Madison and Marianne Plaunt	444
Clinical Endpoint / Sofia Paul	451
Clinical Endpoint BE Studies: Generic Drugs / Stella Grosser, Misook Park, Sam G. Raney, and Elena Rantou	455
Clinical Inspection: Statistical Process / Fuyu Song, Minghuang Hong, and Shein-Chung Chow	462
Clinical Pharmacology / Brian Smith	469
Clinical Research: Benefit and Risk Assessment / Susan Talbot, Shahrul Mt-Isa, Qi Jiang, and Chunlei Ke	472
Clinical Research: Comparing Variabilities / Yonghee Lee, Hansheng Wang, and Shein-Chung Chow	486
Clinical Research: Outlier Detection / Siu-Keung Tse and Liming Xiang	502
Clinical Research: Reproducibility Probability / Shein-Chung Chow	510
Clinical Trial Design: Statistical Assurance / Shuyen Ho	523
Clinical Trial Designs with Prospective Patient Population Enrichment by Response / Anastasia Ivanova, Marc DeSomer, and Jurgen Hummel	526
Clinical Trial Process / Paul F. Kramer	532
Clinical Trial Simulation / Hung-Ir Li and Pan-Yu Lai	536
Clinical Trial Simulations: Earlier Development Phases / Mark Chang	539
Clinical Trial Simulations: Later Development Phases / Mark Chang	544

Clinical Trial: Combination Drug Development / <i>H. M. James Hung</i>	552
Clinical Trial: Failure-Time Model / <i>Chin-Shang Li</i>	556
Clinical Trial: N-of-1 Design Analysis / <i>Can Cui and Shein-Chung Chow</i>	564
Clinical Trials / <i>Kenneth B. Schechtman</i>	572
Clinical Trials: Controversial Issues / <i>Shein-Chung Chow and Fuyu Song</i>	580

Volume II

Clinical Trials: Interval-censored Failure Time Data / <i>Jianguo Sun, Qingning Zhou, and Ding-Geng (Din) Chen</i>	589
Clinical Trials: Investigating Quality-of-Life / <i>Patricia B. Cerrito</i>	597
Clinical Trials: Meta-Analysis using R / <i>Ding-Geng (Din) Chen</i>	603
Clinical Trials: Response-Adaptive Repeated Measurement Designs / <i>Keumhee Carriere Chough and Yuanyuan Liang</i>	612
Clinical Trials: Selection of Control / <i>Irving K. Hwang</i>	622
Clinical Trials: Vaccine Development / <i>Ivan S. F. Chan, William W. B. Wang, and Joseph Heyse</i> ...	628
Cluster Randomized Trials: Sample Size / <i>Sin-Ho Jung</i>	645
Cluster Trials / <i>John S. F. Preisser and Bing Lu</i>	648
Clustered Study Designs: Power Analysis / <i>J. Zhang, C. Feng, W. Tang, X. M. Tu, and J. Kowalski</i> ..	658
Companion Diagnostics / <i>Gene Pennello and Jingjing Ye</i>	672
Comparability Studies: Statistical Considerations / <i>Jason J.Z. Liao, Li He, and Robert Capen</i> ...	682
Confidence Interval and Hypothesis Testing / <i>Ivan S. F. Chan and Devan V. Mehrotra</i>	699
Confounding and Interaction / <i>Catharine B. Stack</i>	703
Content Uniformity / <i>John R. Murphy</i>	709
Continual Reassessment Methods / <i>Xue Lin</i>	712
Contract Research Organization (CRO): Early 2000s / <i>T. Y. Lee</i>	716
Contract Research Organization (CRO) / <i>Tamara Pinkett and Jill Dawson</i>	721
Controlled Clinical Trials: P-Values, Evidence, and Multiplicity Considerations / <i>Mohammad F. Huque, Mohamed Alos, Satya D. Dubey, and Rafia Bhore</i>	725
Correlated Probit Model / <i>Ralitza V. Gueorguieva</i>	741
Cost-Effectiveness Analysis / <i>Heejung Bang</i>	751
Covariate-Adjusted Adaptive Dose-Finding: Early Phase Clinical Trials / <i>Peter F. Thall and Hoang Q. Nguyen</i>	760
Covariates: Adjustment for / <i>Thomas Permutt</i>	772
Crossover Design / <i>Stephen Senn</i>	776
Crossover Design: Rank-Based Robust Analysis / <i>M. Mushfiqur Rashid</i>	784
Cutoff Designs / <i>Joseph C. Cappelleri and William M. K. Trochim</i>	798
Data Mining and Biopharmaceutical Research / <i>Patricia B. Cerrito</i>	805
Data Monitoring Committees (DMC) / <i>Jay Herson</i>	811
Diagnostic Device Evaluation / <i>Meijuan Li, Tinghui Yu, Qin Li, Gene Pennello, R. Lakshmi Vishnuvajjala, Bipasa Biswas, Changhong Song, and Lilly Q. Yue</i>	822
Diagnostic Imaging / <i>Suming W. Chang and Annpey Pong</i>	829
Diagnostic Procedure: Sensitivity and Specificity / <i>Jiayin Zheng and Shein-Chung Chow</i>	836
Disease Modification Effects: Design and Analysis / <i>Djokouri A. Kouassi and Annpey Pong</i>	839
Dissolution Profile Comparison: Statistical Methods / <i>Harry Yang</i>	844
Dissolution Profiles Comparison: Model-Independent Approaches / <i>Yanbing Zheng and Lanju Zhang</i>	854
Dosage Units Using Small and Large Sample Sizes: Uniformity / <i>Meiyu Shen and Yi Tsong</i>	859
Dose Finding Clinical Trials Using R / <i>Naitee Ting and Ding-Geng (Din) Chen</i>	866

Volume II (cont'd.)

Dose Proportionality / <i>C. Gordon Law</i>	876
Dose Response Analysis in Clinical Trials / <i>James MacDougall</i>	879
Dose Response Study Design / <i>Naitee Ting</i>	885
Dose-Ranging Studies: Design Considerations / <i>Qiqi Deng and Naitee Ting</i>	891
Dropout / <i>Cindy Rodenberg, Dan Schnell, and Cameron S. Liu</i>	901
Drug Development / <i>Naitee Ting</i>	908
Drug Interchangeability: Biosimilar Products / <i>Laszlo Endrenyi, Shein-Chung Chow, and Laszlo Tothfalusi</i>	914
Drug Interchangeability: Criteria and Design / <i>Shein-Chung Chow, Fuyu Song, and Meng Chen</i> . .	922
Drug Interchangeability: Meta-Analysis for Safety Monitoring / <i>Wen-Wei Liu and Shein-Chung Chow</i>	928
Drug Interchangeability: Generic Products, Prescribability and Switchability / <i>Laszlo Endrenyi, Shein-Chung Chow, and Laszlo Tothfalusi</i>	935
Ecologic Inference / <i>Sander Greenland</i>	940
ED₅₀/ED₉₀ / <i>Yangxin Huang</i>	952
Enrichment Design / <i>Jen-pei Liu</i>	960
Enrichment Design with Patient Population Augmentation / <i>Yijie Zhou, Bo Yang, Lanju Zhang, and Lu Cui</i>	964
Equivalence Trials / <i>Jen-pei Liu</i>	970
Ethnic Factors / <i>Melody H. Lin and Helen McGough</i>	976
Expiration Dating Period / <i>Annpey Pong</i>	979
Exploratory Factor Analysis / <i>Joseph C. Cappelleri and Robert A. Gerber</i>	985
Extra Variation Models / <i>Jorge G. Morel and Nagaraj K. Neerchal</i>	992
Factor Analysis / <i>Mary D. Sammel, Sarah J. Ratcliffe, and Benjamin E. Leiby</i>	1008
Factorial Designs / <i>Junfang Li</i>	1014
False Discovery Rate (FDR) / <i>Avner Bar-Hen, Philippe Broet, Cyril Dalmasso, Jean-Jacques Daudin, and Stephane Robin</i>	1028
GEE in Cancer Research / <i>Sin-Ho Jung</i>	1036
Generalizability Probability in Clinical Research / <i>Shein-Chung Chow</i>	1042
Generalized Estimating Equation / <i>Myunghee Cho Paik and Hye-Seung Lee</i>	1046
Generalized Inference / <i>Chen-Tuo Liao and Chi-Rong Li</i>	1054
Genetic Linkage and Linkage Disequilibrium Analysis / <i>Kongming Wang, Bernice Porjesz, Henri Begleiter, and Kevin Jones</i>	1057
Global Database and System / <i>Alice T. M. Hsuan and Patrick Genyn</i>	1069
Good Clinical Practice (GCP) / <i>Mamoru Narukawa and Masahiro Takeuchi</i>	1075
Good Laboratory Practice (GLP) / <i>Ying Geng, Baoming Ning, and Dejiang Tan</i>	1082
Good Programming Practice (GPP) / <i>Aileen L. Yam</i>	1088
Good Statistics Practice (GSP) / <i>Shein-Chung Chow</i>	1095
Good Validation Practice (GVP) / <i>Ying Geng and Lan He</i>	1101
Group Sequential Methods / <i>Cheng-Tao Chang</i>	1105
Group Sequential Tests and Variance Heterogeneity:	
Clinical Trials / <i>Keumhee Carriere Chough, Abdulkadir Hussein, and Taesung Park</i>	1114
Human Drug Abuse Trials / <i>Qianyu Dang</i>	1121
Hypothesis Testing / <i>Devan V. Mehrotra and Ivan S. F. Chan</i>	1124
Imputation with Item Nonrespondents / <i>Hansheng Wang and Shein-Chung Chow</i>	1128
Imputation: Clinical Research / <i>Hansheng Wang and Shein-Chung Chow</i>	1135

<i>In Vitro</i> Testing: Bioequivalence / Hansheng Wang, Ying Zhang, Jun Shao, and Shein-Chung Chow . .	1141
<i>In Vitro</i> Testing: Dissolution Profile Comparison / Yi Tsong, Pradeep M. Sathe, and Vinod P. Shah	1148
<i>In Vitro</i> Testing: Micronucleus Test / Wherly P. Hoffman, Michael L. Garriott, and Cindy Lee . . .	1155
Individual Bioequivalence / Shein-Chung Chow and Jen-pei Liu	1160

Volume III

Instrument Development and Validation / Cindy Rodenberg, James T. Kuznicki, and Gloria H. Yiu	1167
Integrated Summary Report / Laura J. Meyerson	1179
Intention-to-Treat Analyses (ITT) / Ronald K. Knickerbocker.	1183
Interchangeability: Generic Drugs / Jiayin Zheng, Shein-Chung Chow, and Mengdie Yuan.	1187
Interim Analysis / Paul Gallo	1195
International Conference on Harmonization (ICH) / Jen-pei Liu and Shein-Chung Chow.	1202
Item Response Theory / Wen-Hung Chen and Joseph C. Cappelleri	1207
IVRS/IWRS for Randomization / Mon-Gy Chen	1216
Japan: Ministry of Health, Labour and Welfare and Pharmaceutical Administration / Kiyohito Nakai	1224
Kaplan–Meier Estimator / Hongyu Jiang and Jason Fine	1231
Kappa Coefficients: Medical Research / Helena Chmura Kraemer.	1237
Kruskal–Wallis Test for Ordered Categorical Data: Power Calculation / Chunpeng Fan and Donghui Zhang	1245
Kullback–Leibler Divergence for Evaluating Equivalence / Vladimir Dragalin	1249
Laboratory Analyses / Michael J. Klepper.	1258
Latent Class Analysis / Elizabeth S. Garrett-Mayer and Jeannie-Marie S. Leoutsakos.	1266
Lilly Reference Ranges / Michael G. Wilson	1276
Local Influence Analysis / Nicola Sartori.	1292
LOCF: Validity / Bin Cheng and Shein-Chung Chow	1296
Logistic Regression / Rick Chappell and Jason Fine	1303
Logistic Regression Process: Predictive Model Building in Clinical Research / Mo Liu and Shein-Chung Chow	1309
Logistic Regression: Three-Point Designs / Mårten Vågerö and Rolf Sundberg	1315
McNemar’s Test / Robert G. Lehr.	1320
MCP-Mod: Dose–Response Testing and Estimation / Björn Bornkamp and Naitee Ting	1326
Measuring Agreement / Lawrence I-Kuei Lin	1335
MedDRA: Impact on Pharmaceutical Development / Keya T. Pitts	1342
Medical Devices / Greg Campbell, Lilly Q. Yue, Gene Pennello, and Mary K. Barrick	1348
Meta-Analysis of Therapeutic Trials / Joseph C. Cappelleri, John P. A. Ioannidis, and Joseph Lau. . .	1362
Microarray Gene Expression / James J. Chen and Chun-Houh Chen	1377
Microdosing Studies / Fuyu Song and Shein-Chung Chow	1394
Minimization Procedure / Dongsheng Tu.	1401
Minimum Effective Dose / Keumhee Carriere Chough.	1406
Mixed Effects Models / Donghui Zhang, Chunpeng Fan, and A. Lawrence Gould	1409
Mixed-Outcome Data / A. R. de Leon.	1414
MMRM with Missing Data / Annpey Pong, Jun Zhao, Allen Lee, Phillip Phiri, and Lev Sverdlov. . .	1422
Modified Large Sample Method / Yonghee Lee.	1427
Multicenter Trials / William J. Huster	1434
Multicollinearity / K. Van Steen and G. Molengerghs	1438

Volume III (cont'd.)

Multidimensional Data Analysis: Penalized Regression Methods / Keumhee Carriere Chough and Xiaoming Wang	1448
Multinational Clinical Trials / Thomas R. Weihrauch	1454
Multiple Comparisons / Mani Y. Lakshminarayanan	1461
Multiple Endpoints / Mario Comelli	1467
Multiple-Dose Bioequivalence Studies / Vernon M. Chinchili	1477
Multiple-Stage Designs: Phase II Cancer Trials / Masha Kocherginsky and Shang P. Lin	1481
Multiplicative Intensity Models / Keumhee Carriere Chough and Abdulkadir Hussein	1494
Multiplicity in Clinical Trials / Peter Westfall and Frank Bretz	1502
Multi-Regional Clinical Trials: Consistency Test / Jiayin Zheng, Lisa Ying, Na Zeng, and Shein-Chung Chow	1511
Multiregional Clinical Trials: Qualitative Consistency of Treatment Effects / Yoko Tanaka and Hiroshi Nishiyama	1522
Multivariate Meta-Analysis / Elizabeth Stojanovski and Kerrie L. Mengersen	1528
Noninferiority Trials: Type I Error Rates / Seung-Ho Kang	1536
Nonparametric Regression / Kongming Wang and Theo Gasser	1543
Odds Ratio / Dongsheng Tu	1554
Oncology Clinical Trials: Efficient Dose-Finding Designs / Erik Rasmussen, Qi Jiang, and Chunlei Ke	1560
Oncology Trials: Development Strategy / Zhaoyang Teng, Yi Liu, Jing Yang, Zhaowei Hua, and Mark Chang	1572
Onset of Action / Thomas R. Stiger and Christy Chuang-Stein	1585
Optimal Futility Interim Design / Zhongwen Tang	1593
Ordered Categorical Data: Test for / Shein-Chung Chow, Siu-Keung Tse, and Chunyan Yang	1602
Ordered Multiple Class Receiver Operating Characteristic (ROC) Analysis / Christos T. Nakas and Constantin T. Yiannoutsos	1608
Ordinal Data: Crossover Design Analysis / Kung-Jong Lui	1613
Parallel Design / Mani Y. Lakshminarayanan	1621
Patient Compliance / Kenneth B. Schechtman	1627
Patient-Reported Outcomes / Amylou C. Dueck and Joseph C. Cappelleri	1633
Percentile Charts on Correlated Measures / Xuming He and Kai W. Ng	1643
Personalized Medicine: Validation of Diagnostic Medical Devices / Meijuan Li, Gene Pennello, Jincao Wu, Laura Yee, Zhiwei Zhang, Gerry Gray, Yuying Jin, Yaji Xu, Jingjing Ye, and Zhiheng Xu	1648
Pharmaceutical Development: Statistical Designs / Annpey Pong and Shein-Chung Chow	1656
Pharmacodynamic Issues / Cheng-Tao Chang and Robert L. Wong	1665
Pharmacodynamics with Covariates / Cheng-Tao Chang and Robert L. Wong	1673
Pharmacodynamics with No Covariates / Cheng-Tao Chang and Robert L. Wong	1685
Pharmacoeconomics / Joseph Heyse, John R. Cook, and Michael F. Drummond	1693
Pharmacoeconomics: Cost-Effectiveness Analysis / Shahram Heshmat	1707
Phase I Cancer Clinical Trials / Seung-Ho Kang and Chul Ahn	1715
Phase II Clinical Development / Naitee Ting and Guojun Yuan	1721
Phase III Clinical Trials with Response-Adaptive Allocation / Atanu Biswas and Rahul Bhattacharyya	1727
Placebo Effect / Thomas R. Stiger and Edward F. C. Pun	1735
Population Bioequivalence / Naitee Ting, Greg C. G. Wei, and William W. B. Wang	1740

Volume IV

Population PK/PD Analysis / <i>D. Concordet, C. Ané, and F. Léger</i>	1747
Postmarketing Adverse Drug Event Signaling / <i>Yi Tsong</i>	1756
Postmarketing Surveillance / <i>Patricia B. Cerrito</i>	1769
Power / <i>Kenneth B. Schechtman</i>	1777
Precision Medicine: Statistical Issues / <i>Fuyu Song and Shein-Chung Chow</i>	1779
Prediction Trees / <i>Antonio Ciampi</i>	1782
Premarket Applications: Registries / <i>Nelson Lu, Yunling Xu, and Lilly Q. Yue</i>	1791
Principal Component Analysis / <i>Aiyi Liu and Enrique F. Schisterman</i>	1796
Process Validation / <i>James S. Bergum and Merlin L. Utter</i>	1802
Profile Analysis / <i>Bin Cheng and Shein-Chung Chow</i>	1817
Propensity Score Analysis and Its Application in Regulatory Settings / <i>Lilly Q. Yue</i>	1823
Propensity Score: Methodology and Application to Clinical Studies / <i>Lilly Q. Yue and Heng Li</i>	1825
Proportion of Treatment Effect / <i>Cong Chen and Hongwei Wang</i>	1830
Proportional Hazards Regression Model / <i>Bee Leng Lee and Jason Fine</i>	1834
Protocol Development / <i>Robert D. Chew</i>	1841
P-Values / <i>Stephen Senn</i>	1845
QT Analysis / <i>Lang Li, Stephen Hall, and Mehul Desai</i>	1855
Quality by Design in Biopharmaceutical Development / <i>Harry Yang</i>	1865
Randomization / <i>Shein-Chung Chow and Jun Shao</i>	1875
Randomized Trials with Clusters: Design and Analysis / <i>Sin-Ho Jung</i>	1880
Rank Regression: Stability Analysis / <i>Annpey Pong, Ying Qing Chen, and Xiudong Lei</i>	1888
Regulatory Statistics / <i>Estelle Russek-Cohen, Tsai-Lien Lin, and Shiohwen Lee</i>	1893
Release Targets / <i>Greg C. G. Wei</i>	1903
Reliability / <i>Valentin Rousson and Theo Gasser</i>	1908
Repeated Measurement Designs: Missing Values / <i>Keumhee Carriere Chough, Yuanyuan Liang, Rong Huang, and Xiaoming Sheng</i>	1918
Repeated Measures Data with Missing Values Analysis: Overview of	
Methods / <i>Keumhee Carriere Chough, Yuanyuan Liang, and Taesung Park</i>	1924
Reproductive and Developmental Studies / <i>James J. Chen</i>	1931
Response Surface Methodology / <i>William R. Myers</i>	1939
Response-Adaptive Designs / <i>Feifang Hu and Anastasia Ivanova</i>	1950
Risk Ratio Analysis / <i>Kung-Jong Lui</i>	1956
ROC Curve / <i>Robert G. Lehr and Annpey Pong</i>	1962
Sample Size Calculation: Nonparametrics / <i>Hansheng Wang and Shein-Chung Chow</i>	1970
Sample Size Calculation: Survival Data / <i>Qi Jiang, Steven Snapinn, and Boris Iglewicz</i>	1980
Sample Size Determination / <i>Lilly Q. Yue, David Li, and Shan Bai</i>	1987
Sample Size Determination: Three-arm Ratio of Mean Differences Equivalence Test / <i>Yu-Wei Chang, Yi Tsong, Xiaoyu Dong, and Zhigen Zhao</i>	2002
Sample Size Estimation: Generalized Estimating Equations (GEE) Method / <i>Sin-Ho Jung</i>	2010
Sample Size for Multiregional Clinical Trials / <i>Yuh-Jenn Wu, Chieh Chiang, Chi-Tian Chen, Hsiao-Hui Tsou, and Chin-Fu Hsiao</i>	2015
Sample Size Re-estimation Based on Observed Treatment Difference / <i>Lu Cui</i>	2021
Sample Size Re-estimation Design with Robust Power / <i>Lu Cui</i>	2026
Sample Size: Negative Binomial With Unequal Follow-Up Times / <i>Yongqiang Tang</i>	2031
Scaled Average Bioequivalence (SABE) / <i>Laszlo Endrenyi and Laszlo Tothfalusi</i>	2038
Screening Design / <i>John R. Murphy</i>	2045

Volume IV (cont'd.)

Seamless Adaptive Trial Design: Dose Selection Criteria / Jiayin Zheng and Shein-Chung Chow . . .	2047
Semi-Parametric Time-Varying Regression Models / Thomas H. Scheike	2058
Sequential Estimation: Additive Hazards Rate Model with Staggered Entry / Laurent Bordes and Christelle Breuils	2063
Signal Detection in Pharmacovigilance / Patrick J. Farrell, Christopher A. Gravel, and Daniel Krewski	2068
Slope Approach: Assessment of Dose Proportionality and Linearity Under a Crossover Design / Bin Cheng and Shein-Chung Chow	2084
Spatio-Temporal Modeling / Ying C. MacNab and Charmaine B. Dean	2089
Specifications / John R. Murphy	2099
SROC Curve / S. D. Walter and Petra Macaskill	2101
Stability Analysis: Frozen Drug Products / Shein-Chung Chow and Jun Shao	2111
Stability Matrix Designs / Earl Nordbrock	2116
Statistical Genetics / Rongling Wu, Guifang Fu, and Hongying Li	2122
Statistical Principles for Clinical Trials / Allan Phillips	2130
Statistical Process Control / William R. Myers and William A. Brennenman	2135
Statistical Significance / Dieter Hauschke, Robert Schall, and Herman G. Luus	2142
Structural Equation Model / Joseph L. Carrasco	2147
Stuart–Maxwell Test / Jiang-Ming Johnny Wu	2154
Subgroup Analysis / Patricia B. Cerrito	2159
Subject-Treatment Interaction / Gary L. Gadbury	2167
Surrogate Endpoint / Shu Zhang and Edward F. C. Pun	2174
Survival Analysis / Dirk F. Moore	2179
Targeted Clinical Trials / Jen-pei Liu	2184
Testing for Qualitative Interaction / Xin Yan and Xiaogang Su	2192
Therapeutic Equivalence / Jen-pei Liu	2199
Thorough QT Studies / Joanne Zhang, Dalong (Patrick) Huang, and Yi Tsong	2206
Tiered Approach of Analytical Similarity Assessment: Statistical Methods / Yi Tsong	2219
Titration Design / Marilyn A. Agin and Edward F. C. Pun	2225
Toxicological Studies / Guenther Baus and Thomas Hoffman	2230
Traditional Chinese Medicine (TCM): Clinical Development / Fuyu Song and Shein-Chung Chow	2244
Traditional Chinese Medicine (TCM): General Considerations / Shein-Chung Chow, Annpey Pong, and Yu-Wei Chang	2252
Traditional Chinese Medicine (TCM): Unified Approach for Evaluation / Bin Cheng and Shein-Chung Chow	2265
Translational Medicine: Concepts, Statistical Methods, and Related Issues / Siu-Keung Tse and Shein-Chung Chow	2270
Trend Estimation / Jian Qing Shi and Man Lai Tang	2283
Two-Stage Adaptive Design: Analysis / Shein-Chung Chow and Min Lin	2289
Two-Stage Design: Phase II Cancer Clinical Trials / Sin-Ho Jung	2296
US Food and Drug Administration / Stacy R. Lindborg and Susan S. Ellenberg	2305
USP Tests / John R. Murphy	2311
Validation of Quantitative and Qualitative Assays / Bob Zhong, Chunfu Qiu, and Dejun Tang . . .	2313
Weibull Model: Group Sequential Design / Jianrong Wu	2325
Z-Score / Jiang-Ming Johnny Wu	2329

Topical Table of Contents

Regulatory Requirement

Regulatory Agency

Canadian Health Products and Food Branch (HPFB) and Therapeutic Products Directorate (TPD) / Dongsheng Tu.	378
US Food and Drug Administration / Stacy R. Lindborg and Susan S. Ellenberg	2305
International Conference on Harmonization (ICH) / Jen-pei Liu and Shein-Chung Chow.	1202
Japan: Ministry of Health, Labour and Welfare and Pharmaceutical Administration / Kiyohito Nakai	1224

Good Pharmaceutical Practices

Data Monitoring Committees (DMC) / Jay Herson	811
Good Clinical Practice (GCP) / Mamoru Narukawa and Masahiro Takeuchi	1075
Good Laboratory Practice (GLP) / Ying Geng, Baoming Ning, and Dejiang Tan	1082
Good Statistics Practice (GSP) / Shein-Chung Chow	1095
Good Programming Practice (GPP) / Aileen L. Yam	1088
Good Validation Practice (GVP) / Ying Geng and Lan He	1101
Regulatory Statistics / Estelle Russek-Cohen, Tsai-Lien Lin, and Shiohjen Lee	1893

Pre-Marketing

Development

Premarket Applications: Registries / Nelson Lu, Yunling Xu, and Lilly Q. Yue.	1791
--	------

Statistical Concepts

Alpha Spending Function / Jihao Zhou and Glen Andrews.	59
Bayesian Statistics / Julia A. Varshavsky and Stacy R. Lindborg.	190
Bootstrap, The / Shein-Chung Chow and Jun Shao	342
Clinical Research: Outlier Detection / Siu-Keung Tse and Liming Xiang	502
Clinical Trial Designs with Prospective Patient Population Enrichment by Response / Anastasia Ivanova, Marc DeSomer, and Jurgen Hummel.	526
Clinical Trials: Selection of Control / Irving K. Hwang	622
Confidence Interval and Hypothesis Testing / Ivan S. F. Chan and Devan V. Mehrotra	699
Confounding and Interaction / Catharine B. Stack.	703
Continual Reassessment Methods / Xue Lin	712
Controlled Clinical Trials: P-Values, Evidence, and Multiplicity Considerations / Mohammad F. Huque, Mohamed Alosch, Satya D. Dubey, and Rafia Bhore	725
Dropout / Cindy Rodenberg, Dan Schnell, and Cameron S. Liu.	901
Extra Variation Models / Jorge G. Morel and Nagaraj K. Neerchal.	992

Statistical Concepts (cont'd.)

False Discovery Rate (FDR) / Avner Bar-Hen, Philippe Broet, Cyril Dalmasso, Jean-Jacques Daudin, and Stephane Robin	1028
Generalizability Probability in Clinical Research / Shein-Chung Chow	1042
Generalized Estimating Equation / Myunghee Cho Paik and Hye-Seung Lee	1046
Generalized Inference / Chen-Tuo Liao and Chi-Rong Li	1054
Hypothesis Testing / Devan V. Mehrotra and Ivan S. F. Chan	1124
Integrated Summary Report / Laura J. Meyerson	1179
Intention-to-Treat Analyses (ITT) / Ronald K. Knickerbocker	1183
Interim Analysis / Paul Gallo	1195
Item Response Theory / Wen-Hung Chen and Joseph C. Cappelleri	1207
Kaplan–Meier Estimator / Hongyu Jiang and Jason Fine	1231
Kappa Coefficients: Medical Research / Helena Chmura Kraemer	1237
Kruskal-Wallis Test for Ordered Categorical Data: Power Calculation / Chunpeng Fan and Donghui Zhang	1245
Kullback–Leibler Divergence for Evaluating Equivalence / Vladimir Dragalin	1249
LOCF: Validity / Bin Cheng and Shein-Chung Chow	1296
Logistic Regression / Rick Chappell and Jason Fine	1303
McNemar’s Test / Robert G. Lehr	1320
MCP-Mod: Dose–Response Testing and Estimation / Björn Bornkamp and Naitee Ting	1326
Measuring Agreement / Lawrence I-Kuei Lin	1335
Minimization Procedure / Dongsheng Tu	1401
Minimum Effective Dose / Keumhee Carriere Chough	1406
Modified Large Sample Method / Yonghee Lee	1427
Multicollinearity / K. Van Steen and G. Molengerghs	1438
Multiple Comparisons / Mani Y. Lakshminarayanan	1461
Multiple Endpoints / Mario Comelli	1467
Multiregional Clinical Trials: Qualitative Consistency of Treatment Effects / Yoko Tanaka and Hiroshi Nishiyama	1522
Noninferiority Trials: Type I Error Rates / Seung-Ho Kang	1536
Nonparametric Regression / Kongming Wang and Theo Gasser	1543
Odds Ratio / Dongsheng Tu	1554
Onset of Action / Thomas R. Stiger and Christy Chuang-Stein	1585
Ordered Categorical Data: Test for / Shein-Chung Chow, Siu-Keung Tse, and Chunyan Yang ..	1602
Placebo Effect / Thomas R. Stiger and Edward F.C. Pun	1735
Power / Kenneth B. Schechtman	1777
Principal Component Analysis / Aiyi Liu and Enrique F. Schisterman	1796
Propensity Score Analysis and Its Application in Regulatory Settings / Lilly Q. Yue	1823
Proportion of Treatment Effect / Cong Chen and Hongwei Wang	1830
P-Values / Stephen Senn	1845
Reliability / Valentin Rousson and Theo Gasser	1908
Repeated Measurement Designs: Missing Values / Keumhee Carriere Chough, Yuanyuan Liang, Rong Huang, and Xiaoming Sheng	1918
Response Surface Methodology / William R. Myers	1939
Risk Ratio Analysis / Kung-Jong Lui	1956

ROC Curve / Robert G. Lehr and Annpey Pong	1962
SROC Curve / S. D. Walter and Petra Macaskill	2101
Statistical Principles for Clinical Trials / Allan Phillips	2130
Statistical Significance / Dieter Hauschke, Robert Schall, and Herman G. Luus	2142
Stuart–Maxwell Test / Jiang-Ming Johnny Wu	2154
Subgroup Analysis / Patricia B. Cerrito	2159
Subject-Treatment Interaction / Gary L. Gadbury	2167
Surrogate Endpoint / Shu Zhang and Edward F. C. Pun	2174
Survival Analysis / Dirk F. Moore	2179
Testing for Qualitative Interaction / Xin Yan and Xiaogang Su	2192
Therapeutic Equivalence / Jen-pei Liu	2199
Trend Estimation / Jian Qing Shi and Man Lai Tang	2283
Z-Score / Jiang-Ming Johnny Wu	2329

Non-Clinical Development

Drug Discovery and Development

Drug Development / Naitee Ting	908
Oncology Trials: Development Strategy / Zhaoyang Teng, Yi Liu, Jing Yang, Zhaowei Hua, and Mark Chang	1572
Pharmaceutical Development: Statistical Designs / Annpey Pong and Shein-Chung Chow. . .	1656

Laboratory Development

Dose Proportionality / C. Gordon Law	876
Laboratory Analyses / Michael J. Klepper	1258
Lilly Reference Ranges / Michael G. Wilson	1276

Analytical Method Development and Validation

Assay Development / Timothy L. Schofield	130
Assay Validation / Timothy L. Schofield	138
Assay Validation: Evaluation of Linearity / Jen-pei Liu and Eric Hsieh	146
Bioassay / Anant M. Kshirsagar	213
Calibration / Shein-Chung Chow	370
Instrument Development and Validation / Cindy Rodenberg, James T. Kuznicki, and Gloria H. Yiu	1167
Validation of Quantitative and Qualitative Assays / Bob Zhong, Chunfu Qiu, and Dejun Tang . .	2313

Process Validation

Comparability Studies: Statistical Considerations / Jason J. Z. Liao, Li He, and Robert Capen. . .	682
Process Validation / James S. Bergum and Merlin L. Utter	1802
Statistical Process Control / William R. Myers and William A. Brenneman	2135

Quality Control and Assurance

Acceptance Sampling / William A. Brenneman and William R. Myers	1
--	---

Quality Control and Assurance (cont'd.)

Specifications / John R. Murphy	2099
Release Targets / Greg C. G. Wei	1903
Quality by Design in Biopharmaceutical Development / Harry Yang.....	1865

USP Tests

Content Uniformity / John R. Murphy	709
Dissolution Profile Comparison: Statistical Methods / Harry Yang	844
Dissolution Profiles Comparison: Model Independent Approaches / Yanbing Zheng and Lanju Zhang.....	854
Dosage Units Using Small and Large Sample Sizes: Uniformity / Meiyu Shen and Yi Tsong ...	859
In Vitro Testing: Dissolution Profile Comparison / Yi Tsong, Pradeep M. Sathe, and Vinod P. Shah.....	1148
In Vitro Testing: Micronucleus Test / Wherly P. Hoffman, Michael L. Garriott, Cindy Lee. ...	1155
USP Tests / John R. Murphy	2311

Stability Analysis

ANCOVA Approach: Premarketing Shelf Life Determination with Multiple Factors / Yi Tsong, Chi-wan Chen, Wen Jen Chen, Roswitha E. Kelly, Daphne T. Lin, and Karl K. Lin	125
Bayesian Methods: Stability Analysis / Jie Chen, Jinglin Zhong, and Lei Nie.....	180
Bracketing Design / John R. Murphy	359
Expiration Dating Period / Annpey Pong.....	979
Stability Analysis: Frozen Drug Products / Shein-Chung Chow and Jun Shao	2111
Stability Matrix Designs / Earl Nordbrock.....	2116
Rank Regression: Stability Analysis / Annpey Pong, Ying Qing Chen, and Xiudong Lei	1888

Pre-Clinical Development
Animal Study

Ames Test / Wherly P. Hoffman and Michael L. Garriott	67
Analysis of Heritability / Brent D. Burch and Ian R. Harris	98

Toxicology Study

Carcinogenicity Studies of Pharmaceuticals / Karl K. Lin.....	398
ED₅₀/ED₉₀ / Yangxin Huang	952
Reproductive and Developmental Studies / James J. Chen	1931
Toxicological Studies / Guenther Baus and Thomas Hoffman.....	2230

Bioavailability and Bioequivalence

Bioavailability and Bioequivalence / Mengdie Yuan and Jingyu Luan Julia.	216
Clinical Endpoint BE Studies: Generic Drugs / Stella Grosser, Misook Park, Sam G. Raney, and Elena Rantou.	455

Drug Interchangeability: Meta-Analysis for Safety Monitoring / Wen-Wei Liu and Shein-Chung Chow	928
Drug Interchangeability: Criteria And Design / Shein-Chung Chow, Fuyu Song, and Meng Chen	922
Drug Interchangeability: Generic Products, Prescribability and Switchability / Laszlo Endrenyi, Shein-Chung Chow, and Laszlo Tothfalusi	935
Drug Interchangeability: Meta-Analysis for Safety Monitoring / Wen-Wei Liu and Shein-Chung Chow	928
In Vitro Testing: Bioequivalence / Hansheng Wang, Ying Zhang, Jun Shao, and Shein-Chung Chow	1141
Individual Bioequivalence / Shein-Chung Chow and Jen-pei Liu	1160
Interchangeability: Generic Drugs / Jiayin Zheng, Shein-Chung Chow, and Mengdie Yuan ...	1187
Multiple-Dose Bioequivalence Studies / Vernon M. Chinchili	1477
Population Bioequivalence / Naitee Ting, Greg C. G. Wei, and William W. B. Wang	1740
Profile Analysis / Bin Cheng and Shein-Chung Chow	1817
Scaled Average Bioequivalence (SABE) / Laszlo Endrenyi and Laszlo Tothfalusi.	2038
Slope Approach: Assessment of Dose Proportionality and Linearity Under a Crossover Design / Bin Cheng and Shein-Chung Chow	2084
Pharmacokinetics and Pharmacodynamics	
Clinical Pharmacology / Brian Smith	469
Pharmacodynamic Issues / Cheng-Tao Chang and Robert L. Wong	1665
Pharmacodynamics with No Covariates / Cheng-Tao Chang and Robert L. Wong	1685
Population PK/PD Analysis / D. Concorde, C. Ané and F. Léger	1747
Sample Size Re-estimation Design with Robust Power / Lu Cui	2026
Bioinformatics	
Bioinformatics / Sean D. Mooney and Jeffrey T. Chang	224
Biomarker Development with Applications to Genetics Data: Statistical Tests / Gang Zheng and Jungnam Joo	243
Data Mining and Biopharmaceutical Research / Patricia B. Cerrito	805
Genetic Linkage and Linkage Disequilibrium Analysis / Kongming Wang, Bernice Porjesz, Henri Begleiter, and Kevin Jones.	1057
Microarray Gene Expression / James J. Chen and Chun-Houh Chen	1377
Statistical Genetics / Rongling Wu, Guifang Fu, and Hongying Li	2122
Clinical Development	
Randomization and Blinding	
Blinding / Shein-Chung Chow and Jun Shao	336
IVRS/IWRS for Randomization / Mon-Gy Chen	1216
Randomization / Shein-Chung Chow and Jun Shao	1875
Sample Size Requirement	
Bayesian Model: Prior Effective Sample Size / Satoshi Morita and Peter F. Thall.	186

Sample Size Requirement (cont'd.)

Blinded Sample Size Re-Estimation / Chien-Hua Wu	323
Cluster Randomized Trials: Sample Size / Sin-Ho Jung	645
GEE in Cancer Research / Sin-Ho Jung	1036
Kruskal-Wallis Test for Ordered Categorical Data: Power Calculation / Chunpeng Fan and Donghui Zhang	1245
Sample Size Estimation: Generalized Estimating Equations (GEE) Method / Sin-Ho Jung	2010
Sample Size for Multiregional Clinical Trials / Yuh-Jenn Wu, Chieh Chiang, Chi-Tian Chen, Hsiao-Hui Tsou, and Chin-Fu Hsiao	2015
Sample Size Calculation: Nonparametrics / Hansheng Wang and Shein-Chung Chow	1970
Sample Size Calculation: Survival Data / Qi Jiang, Steven Snapinn, and Boris Iglewicz	1980
Sample Size Determination / Lilly Q. Yue, David Li and Shan Bai	1987
Sample Size Re-estimation Based on Observed Treatment Difference / Lu Cui	2021
Sample Size: Negative Binomial With Unequal Follow-Up Times / Yongqiang Tang	2031
Sample Size Re-estimation Design with Robust Power / Lu Cui	2026

Clinical Trial

Active Control Non-Inferiority Trials: Hypotheses and False Positive Rate / Gang Chen, George Y. H. Chi, and Yong-Cheng Wang	8
Active Control Trials / George Y. H. Chi, Gang Chen, Mark Rothmann, and Ning Li	14
Bayesian Designs: Phase II Oncology Clinical Trials / Sze Huey Tan, David Machin, and Say Beng Tan	154
Biomarker: Clinical Trials / Mark Chang	251
Cancer Chemotherapy: Maximum Tolerable Dose / Jen-pei Liu	384
Cancer Trials / Clet Niyikiza and Douglas E. Faries	390
Clinical Inspection: Statistical Process / Fuyu Song, Minghuang Hong, and Shein-Chung Chow	462
Clinical Research: Benefit and Risk Assessment / Susan Talbot, Shahrul Mt-Isa, Qi Jiang, and Chunlei Ke	472
Clinical Trial Process / Paul F. Kramer	532
Clinical Trial: Combination Drug Development / H. M. James Hung	552
Clinical Trials / Kenneth B. Schechtman	572
Clinical Trials: Controversial Issues / Shein-Chung Chow and Fuyu Song	580
Cluster Trials / John S.F. Preisser and Bing Lu	648
Equivalence Trials / Jen-pei Liu	970
Group Sequential Tests and Variance Heterogeneity:	
Clinical Trials / Keumhee Carriere Chough, Abdulkadir Hussein, and Taesung Park	1114
Human Drug Abuse Trials / Qianyu Dang	1121
Microdosing Studies / Fuyu Song and Shein-Chung Chow	1394
Multicenter Trials / William J. Huster	1434
Multinational Clinical Trials / Thomas R. Weihrauch	1454
Multiple-Stage Designs: Phase II Cancer Trials / Masha Kocherginsky and Shang P. Lin	1481
Multiplicative Intensity Models / Keumhee Carriere Chough and Abdulkadir Hussein	1494
Multiplicity in Clinical Trials / Peter Westfall and Frank Bretz	1502
Phase I Cancer Clinical Trials / Seung-Ho Kang and Chul Ahn	1715

Phase II Clinical Development / Naitee Ting and Guojun Yuan	1721
Protocol Development / Robert D. Chew	1841

Classical Design

Center Weighting: Multicenter Trials / Paul Gallo	435
Clinical Endpoint / Sofia Paul.	451
Clustered Study Designs: Power Analysis / J. Zhang, C. Feng, W. Tang, X. M. Tu, and J. Kowalski	658
Cutoff Designs / Joseph C. Cappelleri and William M. K. Trochim.	798
Dose Response Study Design / Naitee Ting	885
Dose-Ranging Studies: Design Considerations / Qiqi Deng and Naitee Ting	891
Enrichment Design with Patient Population Augmentation / Yijie Zhou, Bo Yang, Lanju Zhang, and Lu Cui.	964
Extra Variation Models / Jorge G. Morel and Nagaraj K. Neerchal.	992
Factorial Designs / Junfang Li.	1014
Optimal Futility Interim Design / Zhongwen Tang	1593
Ordinal Data: Crossover Design Analysis / Kung-Jong Lui.	1613
Parallel Design / Mani Y. Lakshminarayanan.	1621
Randomized Trials with Clusters: Design and Analysis / Sin-Ho Jung	1880
Screening Design / John R. Murphy	2045
Surrogate Endpoint / Shu Zhang and Edward F. C. Pun.	2174

Innovative Trial Design

Adaptive Design Clinical Trials: Case Studies / Shiohjen Lee and Min Lin.	28
Adaptive Design Methods in Clinical Trials / Shein-Chung Chow and Annpey Pong	36
Adaptive Survival Trials / William F. Rosenberger and Lanju Zhang	50
Clinical Trial: N-of-1 Design Analysis / Can Cui and Shein-Chung Chow	564
Clinical Trials: Response-Adaptive Repeated Measurement Designs / Keumhee Carriere Chough and Yuanyuan Liang	612
Covariate-Adjusted Adaptive Dose-Finding: Early Phase Clinical Trials / Peter F. Thall and Hoang Q. Nguyen.	760
Enrichment Design / Jen-pei Liu.	960
Phase III Clinical Trials with Response-Adaptive Allocation / Atanu Biswas and Rahul Bhattacharya.	1727
Response-Adaptive Designs / Feifang Hu and Anastasia Ivanova.	1950
Seamless Adaptive Trial Design: Dose Selection Criteria / Jiayin Zheng and Shein-Chung Chow	2047
Targeted Clinical Trials / Jen-pei Liu	2184
Two-Stage Adaptive Design: Analysis / Shein-Chung Chow and Min Lin	2289
Two-Stage Design: Phase II Cancer Clinical Trials / Sin-Ho Jung.	2296

Data Management

Clinical Data Management / Terri Madison and Marianne Plaunt.	444
Global Database and System / Alice T. M. Hsuan and Patrick Genyn	1069
Mixed-Outcome Data / A. R. de Leon.	1414

Statistical Methods for Data Analysis

Adverse Event Reporting / Cynthia Pennise	53
Analysis of $2 \times K$ Tables / Shiva Gautam	75
Analysis of Clustered Binary Data / Valerie Durkalski	82
Analysis of Clustered Categorical Data / Kalyan Das	88
Analysis of Variance (ANOVA) / Maria Overbeck-Larisch and Werner Sanns	104
Covariates: Adjustment for / Thomas Permutt	772
Bayesian Estimate: Concordance Correlation Coefficient / Dai Feng, Richard Baumgartner, and Vladimir Svetnik	164
Bayesian Methods: Meta-Analysis / Elizabeth Stojanovski and Kerrie L. Mengersen	173
Bivariate Zero-Inflated Poisson Populations: Statistical Test for Homogeneity / Siu-Keung Tse and Hak-Keung Yuen	316
Case-Control Studies: Inference in / Gary King and Langche Zeng	422
Clinical Research: Comparing Variabilities / Yonghee Lee, Hansheng Wang, and Shein-Chung Chow	486
Clinical Trial: Failure-Time Model / Chin-Shang Li	556
Clinical Trial Design: Statistical Assurance / Shuyen Ho	523
Clinical Trials: Interval-censored Failure Time Data / Jianguo Sun, Qingning Zhou, and Ding-Geng (Din) Chen	589
Clinical Trials: Meta-Analysis using R / Ding-Geng (Din) Chen	603
Correlated Probit Model / Ralitza V. Gueorguieva	741
Cost-Effectiveness Analysis / Heejung Bang	751
Crossover Design: Rank-Based Robust Analysis / M. Mushfiqur Rashid	784
Disease Modification Effects: Design and Analysis / Djokouri A. Kouassi and Annpey Pong ...	839
Dose Finding Clinical Trials Using R / Naitee Ting and Ding-Geng (Din) Chen	866
Dose Response Analysis in Clinical Trials / James MacDougall	879
Ecologic Inference / Sander Greenland	940
Exploratory Factor Analysis / Joseph C. Cappelleri and Robert A. Gerber	985
Factor Analysis / Mary D. Sammel, Sarah J. Ratcliffe, and Benjamin E. Leiby	1008
Good Statistics Practice (GSP) / Shein-Chung Chow	1095
Group Sequential Methods / Cheng-Tao Chang	1105
Hypothesis Testing / Devan V. Mehrotra and Ivan S. F. Chan	1124
Imputation: Clinical Research / Hansheng Wang and Shein-Chung Chow	1135
Imputation with Item Nonrespondents / Hansheng Wang and Shein-Chung Chow	1128
Latent Class Analysis / Elizabeth S. Garrett-Mayer and Jeannie-Marie S. Leoutsakos	1266
Local Influence Analysis / Nicola Sartori	1292
Logistic Regression: Three-Point Designs / Mårten Vågerö and Rolf Sundberg	1315
Mixed Effects Models / Donghui Zhang, Chunpeng Fan, and A. Lawrence Gould	1409
MMRM with Missing Data / Annpey Pong, Jun Zhao, Allen Lee, Phillip Phiri, and Lev Sverdlov	1422
Multidimensional Data Analysis: Penalized Regression Methods / Keumhee Carriere Chough and Xiaoming Wang	1448
Multiplicative Intensity Models / Keumhee Carriere Chough and Abdulkadir Hussein	1494
Multivariate Meta-Analysis / Elizabeth Stojanovski and Kerrie L. Mengersen	1528

Oncology Clinical Trials: Efficient Dose-Finding Designs / Erik Rasmussen, Qi Jiang, and Chunlei Ke	1560
Ordered Multiple Class Receiver Operating Characteristic (ROC) Analysis / Christos T. Nakas and Constantin T. Yiannoutsos	1608
Percentile Charts on Correlated Measures / Xuming He and Kai W. Ng.	1643
Prediction Trees / Antonio Ciampi	1782
Proportional Hazards Regression Model / Bee Leng Lee and Jason Fine.	1834
QT Analysis / Lang Li, Stephen Hall, and Mehul Desai.	1855
Semi-Parametric Time-Varying Regression Models / Thomas H. Scheike.	2058
Sequential Estimation: Additive Hazards Rate Model with Staggered Entry / Laurent Bordes and Christelle Breuils.	2063
Spatio-Temporal Modeling / Ying C. MacNab and Charmaine B. Dean	2089
Structural Equation Model / Joseph L. Carrasco	2147
Thorough QT Studies / Joanne Zhang, Dalong (Patrick) Huang, and Yi Tsong.	2206
Repeated Measures Data with Missing Values Analysis: Overview of Methods / Keumhee Carriere Chough, Yuanyuan Liang, and Taesung Park	1924
Weibull Model: Group Sequential Design / Jianrong Wu.	2325

Post-Marketing

Post Marketing Surveillance

Patient-Reported Outcomes / Amylou C. Dueck and Joseph C. Cappelleri	1633
Postmarketing Adverse Drug Event Signaling / Yi Tsong	1756
Postmarketing Surveillance / Patricia B. Cerrito	1769
Signal Detection in Pharmacovigilance / Patrick J. Farrell, Christopher A. Gravel, and Daniel Krewski.	2068

Outcome Research

Logistic Regression Process: Predictive Model Building in Clinical Research / Mo Liu and Shein-Chung Chow	1309
Pharmacoeconomics / Joseph Heyse, John R. Cook, and Michael F. Drummond	1693

Quality of Life

Clinical Trials: Investigating Quality-of-Life / Patricia B. Cerrito.	597

Preface

In the past decade, there has been explosive growth of literature in biopharmaceutical research and development of new medicines for the treatment of critical diseases that are severe and/or life-threatening. In biopharmaceutical research and development, biopharmaceutical statistics plays an extremely important role in ensuring not only the efficacy and safety of the medicine under investigation but also that the pharmaceutical product possess good drug characteristics such as identity, strength, purity, quality, safety, stability, and reproducibility. The aims of this encyclopedia are to (1) provide a comprehensive and unified presentation of designs and analyses used at different stages of biopharmaceutical research and development, (2) give a well-balanced summary of current regulatory requirements, and (3) describe recently developed statistical methods in the pharmaceutical sciences.

Since the first edition was published in 2000, this encyclopedia has been well received by pharmaceutical scientists/researchers and is now widely used as a reference source in biopharmaceutical research and development. The second edition, published in 2003 included for the first time an online version for easy access by pharmaceutical scientists/researchers and biostatisticians. The third edition was published in 2010 included additional 89 new entries to reach a total of 230 entries in this encyclopedia. The third edition was also available online through the Informa website. This 4th edition can be distinguished from the first three editions in the following ways:

1. Revised and updated entries reflect changes and recent development in regulatory requirements for drug review/approval process and statistical design and methodology.
2. Additional topics have been included to provide a more complete and comprehensive reference source. To name a few, this edition includes important topics such as multiple-stage adaptive trial design in clinical research, biomarker development for target clinical trial for precision medicine, translational medicine, design and analysis of biosimilar drug development, quantitative methods for traditional Chinese medicine development, big data analytics, and real world evidence for clinical research and development. An additional 78 new entries have been contributed by experts in their respective field. As a result, there are now a total of 308 entries in this encyclopedia. This 4th edition will be available online through the Taylor & Francis website.
3. Categorized table of content by stages of biopharmaceutical development provides an easy access to relevant topics in specific stages of biopharmaceutical development.

Although most of the contributors to this encyclopedia are biostatisticians with extensive practical experience in biopharmaceutical research and development, we have attempted to make each entry self-contained and self-explanatory to the reader who is not an expert in the subject matter of each topic. I believe this edition will benefit scientists and researchers from the pharmaceutical and/or biotechnology industry, policymakers, members of regulatory agencies (e.g., EU EMA and US FDA) and government bodies (e.g., US NIH), as well as academia by serving as an extremely useful guide on study protocol and statistical methodology, or indeed the matters of quality control, clinical trial design, risk-benefit analyses, big data analytics, interpretation of results, and formal assessment and appraisal of drugs and pharmaceutical products.

I would like to thank David Grubbs of Taylor & Francis for providing me with the opportunity to work on this edition, and specifically Stephanie DeRosa for her outstanding efforts in coordinating with the contributors during the preparation of this edition. I am deeply indebted to the U.S. Food and Drug Administration (FDA) and many major pharmaceutical companies, including Amgen, Merck, Eli Lilly, Pfizer, Bayer, Novartis, and Bristol-Myers Squibb for their support. I would like to express my gratitude to Dr. Eric Chi (Amgen), Dr. Jiayin Zheng and Dr. Ralph Corey (Duke University School of Medicine), Dr. Laszlo Endrenyi (University of Toronto), and Dr. Lisa LaVange (FDA) for their constant encouragement and support during the process of the preparation of this edition.

Finally, the views expressed in this edition are those of the contributors and not necessarily those of their respective companies or organizations. Any comments and suggestions will be very much appreciated for the preparation of future editions.

About the Editor

Shein-Chung Chow, PhD.

Shein-Chung Chow, PhD. is currently an Associate Director, Office of Biostatistics, U.S. Food and Drug Administration (FDA). Dr. Chow is also a Professor at the Department of Biostatistics and Bioinformatics, Duke University School of Medicine, Durham, NC, and an Adjunct Professor at Duke-NUS, Singapore and North Carolina State University, Raleigh, NC. Dr. Chow is also the Founding Director of the Global Clinical Trial and Research Center, Tianjin, China. Prior to joining Duke University, he was the Director of TCOG (Taiwan Cooperative Oncology Group) Statistical Center and the Executive Director of National Clinical Trial Network Coordination Center. Prior to that, Dr. Chow also held various positions in the pharmaceutical industry such as Vice President, Biostatistics, Data Management, and Medical Writing at Millennium Pharmaceuticals, Inc., Cambridge, MA; Executive Director, Statistics and Clinical Programming at Covance, Inc., Director and Department Head at Bristol-Myers Squibb Company, Plainsboro, NJ. Dr. Chow is the Editor-in-Chief of the Journal of Biopharmaceutical Statistics, Open Access Drug Designing, and the Journal of Biosimilars. Dr. Chow is also the Editor-in-Chief of the Biostatistics Book Series at Chapman and Hall/CRC Press of Taylor & Francis Group. He was elected Fellow of the American Statistical Association in 1995 and an elected member of the ISI (International Statistical Institute) in 1999. He was appointed as a special government employee (SGE) by the FDA in June 2015. In this capacity, Dr. Chow serve as an Oncologic Drug Advisory Committee (ODAC) voting member and a statistical expert consultant to the FDA. Dr. Chow is the author or co-author of over 300 methodology papers and 29 books including Design and Analysis of Bioavailability and Bioequivalence Studies, Statistical Design and Analysis in Pharmaceutical Science, Design and Analysis of Clinical Trials, Design and Analysis of Animal Studies in Pharmaceutical Development, Sample Size Calculations in Clinical Research, Adaptive Design Methods in Clinical Trials, Translational Medicine, Design and Analysis of Bridging Studies, Biosimilars: Design and Analysis of Follow-on Biologics., Quantitative Methods for Traditional Chinese Medicine Development, Biosimilar Drug Product Development, and Statistical Methods for HIV/AIDS Research.

Dr. Chow received a B.S. in mathematics from National Taiwan University, Taiwan, and a PhD. in statistics from the University of Wisconsin, Madison, Wisconsin.

Acceptance Sampling

William A. Brenneman and William R. Myers
The Procter & Gamble Company, Mason, Ohio, U.S.A.

Abstract

This entry summarizes the process and significance of acceptance sampling, which is defined as a statistical tool used to help make decisions concerning whether or not a batch (or lot) of product should be released for consumer consumption or use.

Keywords: Acceptance criteria; Acceptance sampling; Sampling plans.

INTRODUCTION

In general, acceptance sampling is a statistical tool used to help make decisions concerning whether or not a batch (or lot) of product should be released for consumer consumption or use. Acceptance sampling, which will be discussed in this paper, should not be confused with the sampling plans and acceptance criteria mentioned in the United States Pharmacopeia 25 and National Formulary 20.^[1] While acceptance sampling has been used extensively in many industries over the past 60 years, in far too many cases, inspection sampling and quality have been thought of as being synonymous. This is simply not the case because quality stems from a well-designed product produced from a well-designed and capable process. Once the product has been produced and the quality of the product has been fully determined, acceptance sampling can only give us a level of assurance that the product quality is at a certain level and that an Acceptable Quality Level (AQL) will be exposed to consumers. For this reason, the focus in the quality arena has changed from the inspection of finished product quality to the continuous improvement of the product design and process performance.

Although most quality efforts should be put toward the proactive approach found in a continuous quality improvement program, acceptance sampling still plays a practical role. Situations for which acceptance sampling may be useful include incoming inspection with a new supplier for which little is known regarding its capability or quality history; new processes where statistical control is attempted; processes where the quality is relatively poor; and processes that experience flare-ups or special causes (unusual or unexpected result). Furthermore, acceptance sampling is required in current good manufacturing practice (cGMP) in pharmaceutical research and development.^[2] However, the most attractive feature of acceptance sampling is that it allows one to balance two risks: the risk to the producer and the risk to the consumer. These risks need to be fully

understood in order to appreciate acceptance sampling methodology.

An example will be used in order to provide the basic ideas behind acceptance sampling, giving special attention to the producer and the consumer risks. It turns out that these two types of risks uniquely determine a plan, and a thorough understanding of these basic principles will help in understanding more complex plans. Double sampling plans as well as more complex sampling plans are discussed briefly. Variables sampling plans are introduced, and the derivation of their acceptance regions is discussed. Finally, some common misconceptions associated with acceptance sampling plans are presented, and thoughts concerning the use of ANSI/ASQC^[3] sampling procedures are given. Theoretical justification for acceptance sampling is outside the scope of the entry but can be found in Wallis,^[4] Schilling,^[5] and Stephens.^[6] For a historical look at inspection sampling, see Sherman.^[7] Acceptance sampling is reviewed extensively from a Bayesian viewpoint by Wetherill,^[8] Hald,^[9] Moskowitz and Berry,^[10] and Thyregod.^[11] Bayesian cost models are reviewed by Hald,^[12] Guenther,^[13] Lorenzen,^[14] and Wadsworth and Olsen.^[15] Situations where the fraction nonconforming is very low are discussed in Hahn,^[16] Pesotchinsky,^[17] and Moreno and Reeves.^[18] Suich^[19] talks about the effect of inspection errors on the performance of acceptance sampling plans. Finally, the debate concerning all (100%) or nothing (0%) inspection is given by Vander Weil and Vardeman.^[20]

ACCEPTANCE SAMPLING TERMINOLOGY

There are two types of risks that go into creating or evaluating any acceptance sampling plan. The producer's risk is the probability that a lot of product that is at an AQL is rejected by the plan. The AQL is the maximum percent nonconforming that can be considered satisfactory as a process average. On the other hand, the consumer's

risk is the probability that a lot with unacceptable quality is accepted by the plan. The unacceptable quality level is frequently referred to as the Lot Tolerance Percent Defective (LTPD). These four quantities uniquely determine an acceptance sampling plan and can be thought of as the properties (or characteristics) of the plan. In formal hypothesis testing, the terminology used for the producer and the consumer risks are the type I and type II error rates, respectively. In the acceptance sampling literature, plans based on binary data (pass/fail) are referred to as *attribute* acceptance sampling plans, whereas plans based on continuous data are referred to as *variable* acceptance sampling plans. This common terminology will be used throughout. The attribute data could be for the physical evaluation of drug product (e.g., capsule damage, empty capsules, cracked or broken tablets, and coating defects), packaging material (e.g., illegible print) or incoming raw material from a supplier. Examples of variable data are tablet weight, tablet hardness, and bottle measurements.

ACCEPTANCE SAMPLING PLANS FOR ATTRIBUTES

Acceptance sampling plans can be determined from the four quantities: producer's risk, AQL, consumer's risk, and LTPD. For example, consider the creation of a single sampling plan for which the response of interest is an attribute. A single sampling plan then requires determining a sample size n and an acceptance number c . The plan is carried out by counting the number of nonconforming (or defective) units d in a sample of size n and then accepting the lot if $d \leq c$. The sample size and the acceptance number are chosen so that the plan will have the specified properties: producer's risk (α), AQL ($p_1 = \text{AQL}/100$), consumer's risk (β), and LTPD ($p_2 = \text{LTPD}/100$). Assuming that the binomial distribution is an appropriate distribution for modeling the sampling procedure, the sample size n and the acceptance number c are the solutions to the two equations:

$$1 - \alpha = \sum_{d=0}^c \frac{n!}{d!(n-d)!} p_1^d (1 - p_1)^{n-d} \quad (1)$$

$$\beta = \sum_{d=0}^c \frac{n!}{d!(n-d)!} p_2^d (1 - p_2)^{n-d} \quad (2)$$

To be specific, suppose a single sampling plan for cracked tablets calls for a producer's risk of 0.05, an AQL of 1%, a consumer's risk of 0.10, and an LTPD of 5%. Then a sample size of 132 tablets and an acceptance number of 3 are required. To carry out the plan, one would randomly sample 132 tablets from a lot and count the number of cracked tablets found. In practice, this is often done on line. If the number of cracked tablets found is three or less, then the lot is accepted. Otherwise, the lot is rejected.

ACCEPTANCE SAMPLING GRAPHS

An important graph to construct for any sampling plan is called the Operating Characteristic (OC) curve. The OC curve depicts the probability of accepting a lot for a given true, but unknown, defect level. The defect level p is placed on the horizontal axis and the probability of acceptance is placed on the vertical axis. For a single sampling plan for attributes, the probability of acceptance is the probability that d is less than or equal to c , and is given by the expression:

$$P_a = P\{d \leq c\} = \sum_{d=0}^c \frac{n!}{d!(n-d)!} p^d (1 - p)^{n-d} \quad (3)$$

Fig. 1 shows the OC curve for the sampling plan where the sample size is 132 and the acceptance number is 3. The OC curve shows how well a sampling plan does at discriminating between lots with various defect levels. For example, if the true defect level is 2%, then the proposed acceptance sampling plan will have approximately a 73% probability of accepting the lot. That is, if 100 lots from a process that produces 2% defective products are evaluated by the sampling plan, then we can expect, on average, to accept 73 of the lots and reject 27 of them. For a discussion on the effect of a sample size n and an acceptance number c on the OC curve, see Montgomery^[21] or Stephens.^[6]

Another important graph is one that depicts the Average Outgoing Quality (AOQ). The AOQ is the average lot quality that one would expect over time from a process producing fraction defective p . The AOQ only makes sense when the rejected lots are subject to 100% inspection and all non-conforming items are either removed or replaced with conforming items. Such sampling programs are called *rectification inspection programs* because the action of 100% inspection affects the final product quality. Because the only time defective items are released is when

Fig. 1 The OC curve for a single acceptance sampling plan with producer's risk = 5%, AQL = 1%, consumer's risk = 10%, and LTPD = 5%. Sample size, $n = 132$; and acceptance number, $c = 3$

Fig. 2 The AOQ curve for a single acceptance sampling plan with producer's risk = 5%, AQL = 1%, consumer's risk = 10%, and LTPD = 5%. Sample size, $n = 132$; acceptance number, $c = 3$; and lot size, $N = 100,000$

a lot is accepted, it is easy to see that the formula for AOQ is given by:

$$AOQ = \frac{P_a p(N - n)}{N} \quad (4)$$

The AOQ curve for the $c = 3$, $n = 132$ plan where the lot size is $N = 100,000$ units is given in Fig. 2.

Note that the AOQ curve obtains a maximum of 0.015 when the fraction defective is 0.023. This maximum is called the Average Outgoing Quality Limit (AOQL), and it represents the poorest average quality level achievable under a rectification inspection program. This means that no matter what quality level the process is producing, the average defect rate over a large number of lots will be no greater than 1.5%.

The last graph that needs mentioning is the Average Total Inspection (ATI) graph. This graph shows the average number of samples that need to be taken under a rectification inspection program. If lots contain no defective items, then the number of samples per lot will be n , while if the lots contain all defective items then the number of samples will be N . If the proportion of defective items is between these two extremes, then the number of samples will be between n and N . In this case, the ATI per lot is given by the equation:

$$ATI = n + (1 - P_a)(N - n) \quad (5)$$

The ATI graph for the $c = 3$, $n = 132$ plan where the lot size is $N = 100,000$ units is given in Fig. 3.

DOUBLE SAMPLING: NOT AN AD HOC EXTENSION OF SINGLE SAMPLING

Up to this point, we have discussed single sampling plans, where a decision on the lot is based on one sample. However, there are formal double sampling plans whereby,

Fig. 3 The ATI curve for a single acceptance sampling plan with producer's risk = 5%, AQL = 1%, consumer's risk = 10%, and LTPD = 5%. Sample size, $n = 132$; acceptance number, $c = 3$; and lot size, $N = 100,000$

based on the results observed in the initial sample, a second sample may be required. A double sampling plan consists of the following components:

- Sample size of the first sample (n_1);
- Acceptance number for first sample (c_1);
- Rejection number for first sample (r_1);
- Sample size of the second sample (n_2);
- Acceptance number for the first and second samples combined (c_2); and
- Rejection number for the first and second samples combined (r_2 ; $r_2 = c_2 + 1$).

Fig. 4 provides a schematic of the double sampling acceptance plan. The producer's risk, AQL, consumer's risk, and LTPD are the necessary input, as in the case of single sampling, in order to develop a double sampling plan.

The main advantage of double sampling over single sampling is that in most cases, double sampling will reduce the average number of samples (Average Sample Number, ASN) taken. The greatest potential for reducing the average number of samples taken in a double sampling plan is when sampling is stopped (called *curtailment*) when the total number of defects is greater than the second rejection number. To see the relationship between ASN for single and double sampling plans, consider the ASN curve

Fig. 4 Operating flow chart for double acceptance sampling program

Fig. 5 The ASN curve for complete double sampling, curtailed double sampling, and single sampling plans with properties: producer's risk = 5%, AQL = 1%, consumer's risk = 10%, and LTPD = 5%

graphed in Fig. 5. When curtailment is followed, gains in sample size reduction can be made over single sampling plans, but when complete inspection is performed, the gains may not be realized. Another advantage of double sampling plans is that they may give the user a psychological advantage knowing that if the first sample does not allow for acceptance, then the second sample may. The disadvantage of double sampling plans is that they are more complicated to administer.

Double sampling is not an ad hoc extension of single sampling. For example, let us assume that a quality assurance organization instituted a single sampling plan, but decided to take a second sample after the number of nonconforming units observed was greater than the predefined acceptance number. This type of ad hoc double sampling plan results in an inflation of the consumer's risk. Double sampling plans can be extended to multiple sampling plans, whereby more than two samples could possibly be taken. An even greater extension to double and multiple sampling plans is the sequential sampling plan. Schilling^[5] and Stephens^[6] provide an in-depth discussion on these types of sampling plans.

ACCEPTANCE SAMPLING PLAN FOR VARIABLES

Variable acceptance sampling plans are used when the quality characteristic can be measured on a continuous scale. Examples of variables are tablet weight, tablet hardness, and bottle measurements. Variables contain much more information about the quality level than do attributes. For example, if the weight of a tablet is to be between 2 and 6 mg, then reporting that a tablet weighs 2.1 mg is more informative than reporting that the tablets weight is within specification. The fact that much more information can be gained from a variable over an attribute is reason enough to argue that one should never artificially change a variable into an attribute.

The increase in information of a variable over an attribute is the main advantage of variables sampling over

attributes sampling and leads to much smaller sample sizes for variables plans over attributes plans. Consider the example again where it is necessary to have a plan with a producer's risk of 0.05, an AQL of 1%, a consumer's risk of 0.10, and an LTPD of 5%. The variable sampling plan requires only 70 samples, whereas the corresponding attributes sampling plan requires 132 samples.

The main advantage of attributes sampling over variables sampling is that in general, attributes sampling is less time-consuming and requires less expensive testing equipment. Also, the amount of record-keeping and the calculations for variables are often thought of as being more difficult to manage than for attributes. Occasionally, the advantage of simplicity of attribute plans can offset the reduction in sample size due to variables. Another advantage of attribute sampling is that the mathematical assumptions about how quality varies from one item to another are fulfilled as long as a random sample is taken from the lot. On the other hand, the mathematical assumption of variables plans is that quality varies from one item to another in the form of a normal distribution. Whether or not the normal distribution adequately fits the underlying distribution of a variable quality characteristic should be determined through appropriate statistical methods.

Designing a variables sampling plan is similar to designing an attribute sampling plan in that the following four quantities need to be specified: producer's risk (α), AQL ($p_1 = \text{AQL}/100$), consumer's risk (β), and LTPD ($p_2 = \text{LTPD}/100$). From these values, the sample size n and the constant k , which are then used to carry out the plan, can be determined. To carry out the plan, a sample of size n is taken and then the sample mean $\bar{x}$ and sample standard deviation s are calculated. Then for a quality characteristic with a single specification limit, say an USL, the criteria for acceptability is that $\bar{x} + ks \leq \text{USL}$. The formula for k is given by:

$$k = \frac{z_{p_2} z_\alpha + z_{p_1} z_\beta}{z_\alpha + z_\beta} \quad (6)$$

where z_p is the standard normal quantile of the order $(1 - p)$. That is, if $z < N(0,1)$, then $p = \text{Pr}(Z > z_p)$. The formula for n depends on whether or not the variance is assumed to be known or unknown. In general, the recommendation is to assume that the variance is unknown and needs be estimated from the sample because in practice, the variance can change from lot to lot. However, if one has a very large amount of historical data and can show that the variance is constant from lot to lot, then one may wish to assume that the variance is known by using an estimate from the historical data. The result of assuming that the variance is known is a reduction in sample size. When the variance is assumed to be *known*, the formula for n is given by

$$n = \left(\frac{z_\alpha + z_\beta}{z_{p_1} + z_{p_2}} \right)^2 \quad (7)$$

and when the variance is assumed to be *unknown*, the formula for n is given by

$$n = \left(1 + \frac{k^2}{2}\right) \left(\frac{z_\alpha + z_\beta}{z_{p_1} - z_{p_2}}\right) \quad (8)$$

SINGLE-SIDED SPECIFICATION LIMITS

For single-sided specifications, the acceptance regions can be characterized algebraically.

Sigma Known Testing Criteria

- USL: Accept if $\bar{x} + k\sigma \leq \text{USL}$; reject otherwise.
- LSL: Accept if $\bar{x} - k\sigma \geq \text{LSL}$; reject otherwise.

Sigma Unknown Testing Criteria

- USL: Accept if $\bar{x} + k\sigma \leq \text{USL}$; reject otherwise.
- LSL: Accept if $\bar{x} - k\sigma \geq \text{LSL}$; reject otherwise.

TWO-SIDED SPECIFICATION LIMITS

When there are two-sided specification limits, more care needs to be taken in finding the acceptance region. Simply taking the intersection of an LSL acceptance region and a USL acceptance region will not always give the correct acceptance region.

A two-sided acceptance region is most easily shown on a graph. Fig. 6 shows the acceptance region for the plan, assuming unknown variance, with a producer's risk of 0.05, an AQL of 1%, a consumer's risk of 0.10, and an LTPD of 5%. For each sample taken, the sample mean and the sample standard deviation are plotted, and if the point lies below the curve and above the horizontal axis, then the lot is accepted.

Fig. 6 The acceptance region for a variables sampling plan with two-sided specifications (LSL = 10 and USL = 20) and producer's risk = 5%, AQL = 1%, consumer's risk = 10%, and LTPD = 5%

Wallis^[4] provides the mathematical algorithm for finding the acceptance region boundary. The first step is to compute k and n from Eqs. 6 and 7, or Eq. 8. In this case, the p_1 and p_2 values represent the fraction of items outside of the interval LSL-USL. The second step is to find the number p_0 such that $z_{p_0} = k$. The third step is to divide p_0 into two parts p'_0 and p''_0 such that $p_0 = p'_0 + p''_0$. The fourth step is to calculate:

$$\bar{x} = \frac{\text{USL} * z_{p'_0} + \text{LSL} * z_{p''_0}}{z_{p'_0} + z_{p''_0}} \quad \text{and} \quad s = \frac{\text{USL} - \text{LSL}}{z_{p'_0} + z_{p''_0}} \quad (9)$$

which are points that lie on the acceptance region boundary; another point on the acceptance region boundary is $(\bar{x}', s)$ where $\bar{x}' = \text{USL} + \text{LSL} - \bar{x}$.

COMMON ACCEPTANCE SAMPLING MISCONCEPTIONS

One of the most common misconceptions about acceptance sampling plans concerns the misinterpretation of the AQL. Many users of sampling plans interpret the AQL as if it were the LTPD. For example, a user of a sampling plan with an AQL equal to 1% and a producer's risk equal to 5% will often make the incorrect statement that one is 95% confident that the accepted lots have a defect level less than 1%. The correct confidence statement about the defect level of accepted lots needs to be based on the LTPD and the consumer's risk. For example, if the sampling plan just mentioned has an LTPD equal to 5% and a consumer risk equal to 10%, then one can say with 90% confidence that the lots that are accepted have a defect level less than 5%.

Another misconception about sampling plans is that sample size should be proportional to lot size. One incorrect rule of thumb for developing sampling plans is that the sample size should be equal to 10% of the lot size with an acceptance number of zero. The presumption is that following this type of rule provides plans with identical properties for any lot size. However, this is not the case as depicted in Fig. 7, where we have OC curves for two zero acceptance sampling plans that follow the 10% rule. The first plan is derived by assuming a lot size of 10,000 with a sample size of 1,000 and the second plan is derived by assuming a lot size of 1,000 with a sample size of 100. In order for these two plans to have identical properties, their associated OC curves would need to be identical. It is clear from the graph that this is not the case and that the sampling plan with a sample size of 1,000 is much more sensitive to rejecting "poor-quality" lots.

Another misconception encountered is the square root of $N + 1$ (or square root of N) rule for determining the sample size for a sampling plan, where N is the lot size. There is no apparent statistical justification for this rule to be used in general.

Fig. 7 The OC curve for two zero acceptance sampling plans for which sample size is equal to 10% of lot size

The final misconception is that in general, lot size should be used to determine a sampling plan. Theoretically, because all lots are of finite size, the hypergeometric distribution is the one that provides the correct model. The hypergeometric distribution does take into account the lot size and so any acceptance sampling plan developed under the hypergeometric distribution will need to take lot size into consideration. However, in most applications, the binomial distribution approximates the hypergeometric distribution so closely that lot size does not play a *significant* role in determining a sampling plan. A general guideline to determine if lot size should be taken into consideration is to calculate n/N , where n is the sample size and N is the lot size, and to see if this quantity is less than or equal to 0.1. That is, if the sample size is greater than 10% of the lot size, then the lot size should be considered when determining a sampling plan. However, a reasonable approximation is obtained even beyond this guideline.

THOUGHTS ON THE ANSI/ASQC SAMPLING PROCEDURES

Another popular method for developing an acceptance sampling plan is to use the ANSI/ASQC Z1.4: Sampling Procedures and Tables for Inspection by Attributes,^[3] formally the MIL STD 105E. This set of tables allows one to derive an acceptance sampling plan that is based on batch size, inspection level, and AQL. Experience has shown that many of those who implement these plans do not completely understand their properties. These sampling plans are AQL-oriented, in that they focus attention on the producer's risk. This means that as long as the process average of non-conforming units is at or below the pre-specified AQL, the probability of acceptance will be high (at or above 90%). However, these sampling plans do not directly address the consumer's risk and, consequently, do not necessarily reject "poor-quality" lots with high probability. This should be clearly understood by those who use these sampling plans. In order to understand

the consumer's risk, one needs to observe the OC curve for the given sampling plan. There are OC curves available in the ANSI/ASQC Z1.4. Also, a common misuse of ANSI/ASQC Z1.4 is failure to use the switching rule. The general concept of the switching rule is that if lots are continuously accepted, then a "reduced" sampling plan is instituted. However, if lots are continuously rejected, then a "tightened" sampling plan is established. By invoking the switching rules, the consumer risk will be reduced. Consequently, switching rules should be implemented when using these procedures. Finally, we want to mention that tables for deriving variables sampling plans can be found in the ANSI/ASQC Z1.9: Sampling Procedures and Tables for Inspection by Variables for Percent Non-conforming.^[22]

CONCLUSION

Acceptance sampling still has a role in the pharmaceutical industry. In reality, inspection is seen to have value when compared to the catastrophic results of performing no inspection when an unsatisfactory level of quality exists. In addition, acceptance sampling is an audit tool to ensure that the output of a process conforms to requirements. Therefore, it is essential for those implementing acceptance sampling plans to fully understand their properties and to be aware of their common misconceptions. Experience shows that the most common misconception is that the AQL has the interpretation of the LTPD. This may lead to overconfidence in the acceptance sampling plans' ability to reject lots of poor quality. This certainly applies when one selects an acceptance sampling plan from the ANSI/ASQC Sampling Procedure.

Abstract

Hypotheses and False Positive Rate in Active Control Non-Inferiority Trials. The hypotheses in non-inferiority trials involve two unknown parameters. Statistical inferences on non-inferiority hypotheses, ideally, should be based on randomized data collected in the current trial. This entry reviews some of the ethical issues in active control non-inferiority trials and presents statistical models for performing this type of trial.

INTRODUCTION

The purpose of clinical trials in drug development is usually to demonstrate that a new treatment is better than placebo or best supportive care. The hypotheses in such clinical trials involve only one parameter of interest, e.g., treatment effect (relative to placebo or best supportive care). For ethical reason, however, when there are available known effective treatments for the disease, investigators should use one of these active treatments instead of a placebo as the control therapy (declaration of Helsinki^[1]). More and more active controls have been used in clinical trials without a placebo. This naturally leads to an interest in demonstrating the effectiveness of a new treatment through an active control non-inferiority trial. Readers may refer to Chi, Chen, and Rothmann^[2] and Temple^[3] for a discussion of the major issues in the design and analysis of non-inferiority trials. The objective of an active control non-inferiority trial is to demonstrate the efficacy or equivalence of a new treatment through the test of preserving a given fraction or margin of the control effect.

An active control is an intervention such as a drug, therapy, or medical device whose effectiveness has previously been established, mostly based on historical, randomized clinical trials. In an active control non-inferiority trial, the assumption that the active control is effective is fundamental. When this assumption does not hold, a harmful (worse than placebo) drug may be approved based on the results

of non-inferiority test. In current non-inferiority trials, this fundamental assumption has been used either in the formulation or in the inference of the hypotheses. Since the true active-control effect is unknown, the assessment of the fundamental assumption is usually based on historical randomized trials that have demonstrated positive control effect. However, the conclusion of those trials may be falsely positive, and the false positive rate for claiming the control effect in those trials is usually controlled at a given significance level, say 5%. In other words, the assumption may be wrong with a certain probability. A wrong assumption may lead to an invalid non-inferiority trial design and a false positive conclusion. The false positive rate associated with the objective of a non-inferiority trial may not be correctly assessed if the assumption is wrong. We discuss in this paper various possible hypotheses formulated in non-inferiority trials. The false positive rate for concluding non-inferiority is evaluated through a simulation. The hypotheses appropriately associated with the objective of a non-inferiority trial are suggested.

HYPOTHESES IN ACTIVE CONTROL NON-INFERIORITY TRIALS

Since there are two parameters involved in non-inferiority hypotheses, the hypotheses can be formulated in different ways. The appropriateness of the hypotheses is dependent on the objective of the non-inferiority trial. In this section, we present the possible hypotheses in non-inferiority trials and discuss their appropriateness in terms of the parameter spaces under the null and the alternative hypotheses.

The views expressed in this entry are those of the authors and not necessarily those of the U.S. Food and Drug Administration.

Parameter Space

In order to understand non-inferiority hypotheses and the associated probability of the type I error, in this section, we present parameter spaces under the null and the alternative non-inferiority hypothesis. Let T and C denote the new treatment and active control, respectively. The concepts and issues are discussed here within the framework of a randomized trial comparing the survival experience of a new treatment T to a single active control C in treating patients with a serious disease. Let the true hazard ratio of T relative to C be denoted by $HR(T/C)$. We define the fraction loss of control effect as

$$1 - \delta = [HR(T/C) - 1] / [HR(P/C) - 1] = \theta_t / \theta_c$$

where $\theta_t = HR(T/C) - 1$, $\theta_c = HR(P/C) - 1$, and P stands for the reference placebo. In the definition of the fraction loss $(1 - \delta)$, θ_c represents the control effect (relative to placebo) and θ_t the treatment effect relative to the control. Fig. 1 shows the partition of two coordinate systems $(HR(P/C), HR(T/C))$ and (θ_c, θ_t) , respectively. Coordinate system (θ_c, θ_t) is a location shift of the coordinate system $(HR(P/C), HR(T/C))$.

In Fig. 1, the relationship between the two treatments, T and C , is presented in each subspace. The notation “>” used in Fig. 1 and the following figures stands for “better than.” Since the primary interest in a non-inferiority trial is to test whether the new treatment T is effective, an ideal parameter space under the alternative in non-inferiority hypotheses should contain the subspace that $T > P$ (T is better than P).

Superiority Hypotheses for Treatment and Control Effect

If there is a placebo arm in the trial, the effectiveness of the new treatment T can be demonstrated through comparison with the placebo using the following superiority hypotheses:

$$H_0 : \mu_t \leq 1 \quad \text{vs.} \quad H_a : \mu_t > 1 \quad (1)$$

where $\mu_t = HR(T/P)$ denotes the hazard ratio of treatment vs. placebo.

When placebo cannot be used in a trial due to ethical concern, the effectiveness of a new treatment T needs to be

Fig. 1 The partition of the parameter space

demonstrated through proving either that T is superior to the active control C , or that T is non-inferior to C . The term “non-inferior” means that the new treatment T preserves a fraction of the control effect or the new treatment is not worse than control by a given (fixed) margin, assuming the control is effective. Unless the new treatment represents a significant therapeutic advance, in general it would be difficult for it to show superiority to the active control.

The control effect θ_c is usually assessed in randomized, historical trials with superiority hypotheses:

$$H_0 : \theta_c \leq 0 \quad \text{vs.} \quad H_a : \theta_c > 0 \quad (2)$$

If the effectiveness of the control has been demonstrated in those historical trials, one may consider a non-inferiority design of a trial.

Ratio Non-Inferiority Hypotheses

A non-inferiority hypothesis generally involves two parameters, i.e., treatment effect θ_t and control effect θ_c . The direct translation of the non-inferiority objective to statistical hypotheses is the following ratio hypotheses:

$$H_0 : \theta_t / \theta_c \geq 1 - \delta_0 \quad \text{vs.} \quad H_a : \theta_t / \theta_c < 1 - \delta_0 \quad (3)$$

where δ_0 ($0 \leq \delta_0 \leq 1$) denotes a given level of fraction retention.

Fig. 2 presents the parameter space under the null and the alternative of the ratio hypotheses in (3).

In some clinical settings, one may fix the control effect in non-inferiority hypotheses, i.e., $\theta_c = M_1 > 0$, and formulate a fixed margin non-inferiority hypotheses. The validity of the fixed margin hypotheses depends on the assumption $\theta_c > 0$. If this assumption does not hold, the fixed margin hypotheses are not valid for a non-inferiority trial. In the fixed margin setting, the ratio non-inferiority hypotheses can be simplified to hypotheses with one parameter:

$$H_0 : \theta_t / M_1 \geq 1 - \delta_0 \quad \text{vs.} \quad H_a : \theta_t / M_1 < 1 - \delta_0$$

where $\theta_t = HR(T/C) - 1$.

Fig. 2 The parameter space under the null and alternative hypotheses in (3)

Since $M_1 > 0$, the above hypotheses are equivalent to

$$\begin{aligned} H_0 : \text{HR}(T/C) &\geq 1 + M \quad \text{vs.} \\ H_a : \text{HR}(T/C) &< 1 + M \end{aligned}$$

where $M = M_1(1 - \delta_0) > 0$ is the margin defined based on control effect.

Fixed margin hypotheses have been used in some oncology trials with the response rate as the primary endpoint, as well as in thrombolysis trials.^[7] The interpretation of the fixed margin hypotheses and fraction retention hypotheses are different. A detailed discussion is given in Refs. [2,4].

Linear Transformation

Since it is difficult to draw a statistical inference on such ratio hypotheses, a transformation of the ratio hypothesis is often needed. In the paper by Rothmann et al.,^[4] the following linear hypotheses were formulated:

$$\begin{aligned} H_0 : \theta_t - (1 - \delta_0)\theta_c &\geq 0 \quad \text{vs.} \\ H_a : \theta_t - (1 - \delta_0)\theta_c &< 0 \end{aligned} \quad (4)$$

The assumption that $\theta_c > 0$ is used to show how the linear hypotheses in (4) are evolved from the definition of fraction retention (ratio hypotheses). This assumption is not used in the inference of the linear hypotheses.^[4,5] The parameter spaces under the null and the alternative hypothesis in (4) are presented in Fig. 3.

Fig. 3 illustrates that the parameter space under the alternative hypothesis in (4) contains an inappropriate subset $C < T < P$, which should be located in the parameter space under the null hypothesis in non-inferiority trials. The claim of non-inferiority based on the rejection of the null hypotheses in (4) leads to an incorrect assessment of the false positive rate.

It is questionable to make the assumption $\theta_c > 0$ in the formulation of non-inferiority hypotheses. Fig. 4 presents the parameter spaces under the null and the alternative hypothesis in (4) with the assumption that $\theta_c > 0$.

Fig. 3 The parameter space under the null and alternative hypotheses in (4)

Assuming $\theta_c > 0$, the parameter space under the hypotheses has been reduced, i.e., the left column ($\theta_c < 0$) in the parameter space has been truncated. The shaded area is the parameter space under the null hypothesis in (4) with the assumption that $\theta_c > 0$. The non-inferiority hypotheses with this reduced parameter space ($\theta_c > 0$) are questionable since the data for the statistical inference of the hypotheses are sampled from distributions with population parameters for the control and the treatment over the entire parameter space ($\text{HR}(P/C) > 0$, $\text{HR}(T/C) > 0$). The reduction of the parameter space leads to an inappropriate statistical inference for a non-inferiority trial.

If $\theta_c > 0$ does not hold, the hypotheses in (4) are not appropriate for non-inferiority trials since the parameter space under the alternative contains the subset that $T < C < P$, i.e., the new treatment is inferior to placebo. This subset should be located in the parameter space under the null in non-inferiority trials.

Other Type of Transformation

To avoid using the assumption that $\theta_c > 0$, one may have another type of transformation of a non-inferiority hypothesis. For example, Wang, Chen, and Chi^[6] considered the following transformation of non-inferiority hypotheses:

$$\begin{aligned} H_0 : \ln(\theta_t/\theta_c + k)^2 &\geq \eta \quad \text{vs.} \\ H_a : \ln(\theta_t/\theta_c + k)^2 &< \eta \end{aligned} \quad (5)$$

where $k > 0$ and $\eta > 0$. The details of the hypotheses test are not discussed in this article.

Union Non-Inferiority Hypotheses

As discussed above, both linear and ratio hypotheses are not appropriate for a non-inferiority trial in terms of the partition of their parameter spaces under the null and

Fig. 4 The parameter space under the null and alternative hypotheses in (4) with the assumption $\theta_c > 0$

the alternative hypothesis. The following union hypotheses for non-inferiority trials may be considered:

$$\begin{aligned} H_0 &: \{\theta_t - (1 - \delta_0)\theta_c \geq 0\} \cup \{\theta_c \leq 0\} \quad \text{vs.} \\ H_a &: \{\theta_t - (1 - \delta_0)\theta_c < 0\} \cap \{\theta_c > 0\} \end{aligned} \quad (6)$$

Fig. 5 presents the parameter spaces under the null and the alternative hypothesis in (6).

The hypotheses in (6) fit the objective of non-inferiority trials. The parameter space under the alternative contains both subsets $P < T < C$ and $T > C > P$, i.e., the new treatment is either better than the active control or preserves a fraction of the control effect (non-inferior to the active control).

If the purpose of a non-inferiority trial is only to demonstrate that the experimental treatment is effective, the hypotheses may be formulated as follows:

$$\begin{aligned} H_0 &: \{\theta_t/\theta_c \geq 1 - \delta_0\} \cup \{\{\theta_c \leq 0\} \cap \{\theta_t/\theta_c \geq 1\}\} \\ \text{vs.} \\ H_a &: \{\theta_t/\theta_c < 1 - \delta_0\} \cap \{\{\theta_c > 0\} \cup \{\theta_t/\theta_c < 1\}\} \end{aligned} \quad (7)$$

Fig. 6 presents the parameter spaces under the null and the alternative hypothesis in (7).

Fig. 5 The parameter space under the null and alternative hypotheses in (6)

Fig. 6 The parameter space under the null and alternative hypotheses in (7)

The hypotheses in (7) may be ideal for testing the efficacy of the new treatment through a non-inferiority trial, since the parameter space under the alternative contains the entire subset $T > P$.

Of the above non-inferiority hypotheses, the hypotheses in (6) may be appropriately associated with the objective of a non-inferiority trial. The rejection of the null in (6) leads to the conclusion that the new treatment is effective. However, since the statistical inference for both hypotheses (6) and (7) involves a direct comparison of treatment with placebo, which is not available in the trial, the validity of the statistical inference is the major concern.

FALSE POSITIVE RATE CONSIDERATION

Since the assessment of the control effect θ_c is based on data collected from randomized historical trials, the evaluation of the false positive rate associated with the non-inferiority test procedure for claiming non-inferiority should consist of two components. The first component is the probability of wrong rejection of the null in the non-inferiority hypotheses in current non-inferiority trial. The second component is the probability that the control is not effective as assessed in historical trials. In current non-inferiority trials, however, the probability that the control is not effective has not been taken into the consideration in the non-inferiority test procedure. More discussion is given in the following section. As an example, in section “Simulation,” the simulation results demonstrate the magnitude of the false positive rate inflation associated with the non-inferiority test procedure when using the linear non-inferiority hypotheses in (4) under the assumption that the control is effective.

Non-Inferiority Test Procedure

In a non-inferiority trial, linear hypothesis (4) ($H_0^{(4)}$) has often been formulated for testing a fraction retention of control effect. The non-inferiority test procedure can be described as follows. The first step is to assess the control effect, i.e., to test the hypothesis in (2) ($H_0^{(2)}$). If the $H_0^{(2)}$ is rejected at a prespecified α_1 level, e.g., 0.05, we conclude that the control is effective and then further test the non-inferiority hypothesis in $H_0^{(4)}$ in a non-inferiority trial. If $H_0^{(4)}$ is rejected at a prespecified α level, e.g., 0.05, we conclude “non-inferiority.” The non-inferiority test procedure is described in Fig. 7.

False Positive Rate

To assess the false positive rate, we denote by α_1 a prespecified Type I error rate for testing $H_0^{(2)}$, and α a prespecified Type I error rate for testing $H_0^{(4)}$. According to Fig. 7, the

Fig. 7 Flowchart for a non-inferiority trial test procedure

false positive rate associated with the non-inferiority test procedure can be defined as below.

$$\begin{aligned}\alpha^* &= \Pr(\text{reject } H_0^{(4)} | H_0^{(4)} \text{ and control is truly positive}) \\ &\quad + \Pr(\text{reject } H_0^{(4)} | H_0^{(4)} \text{ and control is truly negative}) \\ &= \alpha + \alpha_0\end{aligned}$$

Simulation

The simulation in this section is to demonstrate the false positive rate associated with the non-inferiority test procedure when the type I error rate under linear hypothesis $H_0^{(4)}$ is controlled at a prespecified level α .

The following assumptions are used in the simulation. Let $X_1, X_2, \dots, X_m$ be independent random variables with normal distribution $N(\theta_c, 1)$, and $Y_1, Y_2, \dots, Y_n$ be independent random variables with normal distribution $N(\theta_t, 1)$, where $\theta_t = (1 - \delta_0) \theta_c$ and $0 \leq \delta_0 \leq 1$ is a constant (fraction retention). The simulation is based on 500,000 runs and both $n = m = 1000$ and $\theta_c = 0$. We define α^* to be the false positive rate associated with the non-inferiority test procedure, and we assume $\alpha_1 = \alpha = 0.05$. The simulation results are listed in Table 1.

Table 1 The False Positive Rate α^* Associated with Non-inferiority Test Procedure

δ_0	α_1	α	α^*
0	0.0499	0.0501	0.0697
0.25	0.0498	0.0503	0.0656
0.5	0.0501	0.0503	0.0607
0.75	0.0504	0.0502	0.0560
1	0.0506	0.0504	0.0526

The results in Table 1 show that the false positive rate associated with the non-inferiority test procedure is much greater than the prespecified level of Type I error α under hypothesis $H_0^{(4)}$. This inflation is attributed to the nonzero Type I error rate α_1 under hypothesis $H_0^{(2)}$ for testing the control effect in historical trials. The higher significance level specified in testing control effect results in the lower false positive rate associated with the non-inferiority test procedure. The selection of the higher fraction retention (δ_0) also results in the lower false positive rate.

Superiority Test Based on Non-Inferiority Hypothesis

From Table 1, the false positive rate inflation relative to α (type I error rate) under hypothesis $H_0^{(4)}$ is at least 0.0025 even when $\delta_0 = 1$, i.e., the new treatment is superior to control. The reason for such inflation is that we use non-inferiority hypotheses for the superiority test $T > C$. The false positive rate associated with the non-inferiority test procedure is not only controlled for testing $T > C$ (treatment is superior to control), but also controlled for testing $C > P$ (control is effective). The following two figures illustrate the parameter spaces under the null and the alternative for the superiority hypotheses in (8) and the non-inferiority hypotheses in (9) for testing whether the treatment is superior to the control.

Fig. 8 presents the parameter space under the null and the alternative for the following superiority hypotheses:

$$H_0 : \theta_t \geq 0 \quad \text{vs.} \quad H_a : \theta_t < 0 \quad (8)$$

Fig. 9 presents the parameter space under the null and alternative for the following non-inferiority hypotheses:

$$\begin{aligned}H_0 : \{\theta_t \geq 0\} \cup \{\theta_c \leq 0\} \quad \text{vs.} \\ H_a : \{\theta_t < 0\} \cap \{\theta_c > 0\}\end{aligned} \quad (9)$$

The superiority of T over C can be demonstrate based on either hypothesis (8) or (9). The higher Type I error rate

Fig. 8 The parameter space under the null and alternative hypotheses in (8)

Fig. 9 The parameter space under the null and alternative hypotheses in (9)

associated with non-inferiority hypotheses (9) is because the parameter space under the null in (9) contains the subset $\{\theta_c \leq 0\} \cap \{\theta_t \leq 0\}$, which is located in the parameter space under the alternative in (8).

CONCLUSIONS AND DISCUSSION

The objective of an active control non-inferiority trial is to demonstrate the effectiveness or non-inferiority of a new treatment through comparison with an active control. The hypotheses in non-inferiority trials involve two unknown parameters. Statistical inferences on non-inferiority hypotheses, ideally, should be based on randomized data collected in the current trial. Due to ethical considerations, however, there is no placebo arm included in current non-inferiority trials, and the inference on the control effect is usually based on historical randomized data. There have been intensive discussions on those issues when involving nonconcurrent randomized trial data in the current statistical inference of non-inferiority hypotheses.^[2-5] The major issues include whether the patient population used in historical trials is similar to that used in the current non-inferiority trial in terms of patients characteristics, whether the control effect has changed over time (the constancy of the control effect), whether the best supportive care has been changed, etc. Therefore, the design of a non-inferiority trial should be done on a case-by-case basis. We need to have assurance that the type I error in the historical randomized trials for testing active-control effect is well controlled. We should have multiple historical randomized placebo controlled studies that show relatively consistent results.

If the claim of non-inferiority is based on testing the linear null hypothesis in (4) using the test statistic Z as

defined in,^[4] it generally inflates the false positive rate associated with the non-inferiority test procedure. This has been demonstrated from simulation. Since the control effect is tested based on historical trials, we cannot guarantee that the true control effect may not be negative. For a fraction retention hypothesis, the assumption that $\theta_c > 0$ is only used to show how the linear null hypothesis in (4) is evolved from the definition of fraction retention.^[4] However, it is critical to note that for fixed margin hypotheses, it is essential that the assumption, $\theta_c > 0$, hold; otherwise, one cannot define a positive margin. Therefore, fixed margin hypotheses would be appropriate only when either the control effect is very large, or the control effect cannot be negative, as in tumor response rate.

When designing a non-inferiority trial, the hypotheses in (4) can be formulated. The advantage of using the linear hypotheses in (4) is that statistical inference is simple. However, if the non-inferiority conclusion is based on the rejection of the null hypothesis in (4), the type I error rate should be appropriately adjusted to control the false positive rate associated with the non-inferiority test procedure at a pre-specified level. For example, based on the result given in Table 1, if the linear hypotheses in (4) are used to test 50% retention of the control effect, i.e., $\delta_0 = 0.5$, to control the false positive rate associated with the non-inferiority test procedure for the claim of “non-inferiority” at 0.05 level, the nominal α under $H_0^{(4)}$ should be prespecified at a significance level of $0.05/0.0609 = 0.041$.

Abstract

An active control is an intervention, such as a drug, a therapy, or a medical device, whose effectiveness has previously been established. This entry will discuss the basic issues associated with an active control trial, and some of the issues attendant with the current methods that are used in the design and analysis of active control trials.

Keywords: Active control trials; Non-inferiority hypotheses; Sample size; Superiority hypotheses.

INTRODUCTION

An active control is an intervention, such as a drug, a therapy, or a medical device, whose effectiveness has previously been established. Active controls have been used in trials with or without a placebo. For clinical drug trials with a placebo, sometimes called trials with a gold standard design, active controls usually play a secondary role with respect to demonstrating the effect of a new treatment. In placebo control trials involving psychotropic agents, active controls are intended for the purpose of verifying the assay sensitivity of the trials (Leber^[1,2]), i.e., the ability of the trial to demonstrate an effective drug to be effective (ICH-E10^[3]). In this article, active control trial with a gold standard design will not be considered; an active control trial refers specifically to a trial with a control that is known to be effective and without the presence of a placebo. Active control trials often arise when the objective of a trial is to investigate the effect of the new treatment on mortality or serious morbidity outcome for patients with certain serious diseases. For obvious ethical reason, when there are available known effective treatments for the disease, one should use one of these active treatments instead of a placebo as the control (Declaration of Helsinki^[4]). This article will discuss the basic issues associated with an active control trial, and some of the issues attendant with the current methods that are used in the design and analysis of active control trials. The concepts and issues will be discussed within the framework of a blinded, parallel, randomized trial comparing the survival experience of a new treatment, T , to a single active control, C , in treating patients with certain serious disease.

OBJECTIVE OF AN ACTIVE CONTROL TRIAL

The primary objective of an active control trial is to demonstrate the effectiveness of a new treatment, T . To show that a new treatment, T , is effective, traditionally, it is required to demonstrate that T is superior to C , the active control. This is analogous to a placebo control trial where the new treatment, T , has to show superiority to the placebo. It often happens that upon failing to demonstrate superiority in such a trial, the experimenter then concludes that the new treatment is equivalent, similar, or non-inferior to the active control. However, this reasoning is fallacious because in a superiority trial, failing to reject the null hypothesis of inferiority or no difference does not imply that the null hypothesis is true. Unless the new treatment represents a significant therapeutic advance, in general, it would be difficult for the new treatment to show superiority to the active control. This naturally leads to an interest in demonstrating the effectiveness of a new treatment through an active control non-inferiority (or a one-sided equivalence) trial, whereby the new treatment is shown to be equivalent or no worse than the active control by a certain equivalence or non-inferiority margin δ . The question then is how does one determine this margin δ ? One may refer to Temple,^[5] EMEA^[6] and FDA^[7] for a discussion of some of the problems involved in the interpretation of active control trials. In the following sections, we will discuss how the two current methods arrive at the determination of this margin and the problems associated with these methods.

THE BASIC ASSUMPTIONS IN AN ACTIVE CONTROL TRIAL

The first critical assumption implicit in any active control trial is that the active control is still effective in the current setting. This assumption cannot be verified short of the inclusion of a placebo in the active control trial. If one doesn't believe that the active control is effective in the current setting, then one should either use a different active control that is believed to be effective in the current setting, or else demonstrates that the new treatment is superior to the active control. Therefore, for this reason as well as for obvious ethical reasons, one should use the most effective active control currently available as the control. With such an active control, one can at least feel more assured that the active control is effective in the present setting.

The second critical assumption that is also implicit in any active control trial is that the trial has assay sensitivity. Assay sensitivity refers to the ability of a trial to distinguish an effective treatment from an ineffective treatment. Without assay sensitivity, a trial cannot even detect the effect of a control that is known to be effective. Thus, with the first assumption, the active control is assumed to be effective in the current trial setting, and with assay sensitivity, the trial should be able to detect the effect of this control. In addition, if the new treatment is ineffective, then this trial should be able to differentiate it from the control.

There are generally two current methods to the determination of a non-inferiority margin. The first approach is termed the fixed margin method, and the second approach is called the fraction retention method, or sometimes termed the synthesis method (Hung et al.^[8–10] and Ng^[11]). Both assumptions are needed in the two methods. However, as will be noted later, the first assumption is implicitly made in each method in a different way.

HYPOTHESES OF AN ACTIVE CONTROL TRIAL

Let the true hazard ratio of T relative to C be denoted by $HR(T/C)$, and let $hr(T/C)$ denote its estimator. Let P denote the reference or imputed “placebo,” and $HR(P/C)$ and $hr(P/C)$ denote the corresponding hazard ratios.

Superiority Hypotheses

If there is reason to believe that the new treatment, T , represents a true therapeutic advance and one wishes to demonstrate the superiority of T over C , then the null and alternative hypotheses are simply,

$$H_0 : \log HR(T/C) \geq 1 \quad \text{vs.} \quad H_a : HR(T/C) < 1.$$

In terms of log hazard, these hypotheses may be stated as,

$$\begin{aligned} H_0 : \log HR(T/C) &\geq 0 \quad \text{vs.} \\ H_a : \log HR(T/C) &< 0 \end{aligned} \quad (1)$$

The null hypothesis in Eq. 1 may be tested by the following test statistic:

$$\tau_0 = \frac{\log hr(T/C)}{SE[\log hr(T/C)]} \quad (2)$$

where SE stands for “standard error.” The null hypothesis in Eq. 1 is rejected if $\tau_0 < -1.96$ (Wald's test), or equivalently, if $\log hr(T/C) + 1.96SE[\log hr(T/C)] < 0$, at the one-sided 2.5% significance level. As in a placebo control trial, in an active control superiority trial, there is only one parameter that will be tested. In the case here, this parameter is the log-hazard ratio, $\log HR(T/C)$, of the new treatment relative to the control.

However, if the new treatment is only as effective as the control, then the null hypothesis in Eq. 1 is unlikely to be rejected. One may not conclude that the new treatment is non-inferior (or equivalent) to the control upon failing to reject this null hypothesis, since failing to reject the null hypothesis in Eq. 1 does not imply that the null hypothesis is true.

Non-inferiority Hypotheses with a Fixed δ Margin

When the new treatment is thought to be as effective as the control and the objective of the trial is to demonstrate the effectiveness of this new treatment by showing that it is non-inferior to the control, then the null and alternative hypotheses may be stated as follows:

$$\begin{aligned} H_0 : HR(T/C) &\geq 1 + \delta \quad \text{vs.} \\ H_a : HR(T/C) &< 1 + \delta. \end{aligned}$$

where $\delta > 0$ is a fixed non-inferiority margin.^[12]

Again, in terms of log hazard, these hypotheses may be stated as follows:

$$\begin{aligned} H_0 : \log HR(T/C) &\geq \delta \quad \text{vs.} \\ H_a : \log HR(T/C) &< \delta \end{aligned} \quad (3)$$

where $\delta > 0$ is a fixed non-inferiority margin (this δ is different from the δ above) (See Remark 3).

The null hypothesis in Eq. 3 may be tested by the following test statistic.

$$\tau_0(\delta) = \frac{[\log hr(T/C) - \delta]}{SE[\log hr(T/C)]} \quad (4)$$

The null hypothesis in Eq. 3 is rejected if $\tau_0(\delta) < -1.96$, or equivalently, if $\log hr(T/C) + 1.96SE[\log hr(T/C)] < \delta$,

at the one-sided 2.5% significance level. One may then conclude that the new treatment is non-inferior to the active control within this fixed margin δ . The question is how should this δ margin be determined?

If the margin δ is arbitrarily selected, then the rejection of the null hypothesis in Eq. 3 may actually lead to the conclusion that a new treatment is non-inferior to the control when, in reality, it is worse than a placebo. This can easily be seen from the following scenario. Assume that in the current trial, the true hazard ratio is known and is given by $HR(P/C)$. If the margin δ is specified so that it is greater than the effect of the control, i.e., $\delta > \log HR(P/C)$, then the rejection of the null hypothesis in Eq. 3 does not rule out the possibility that the new treatment can be worse than the placebo, i.e., $\log HR(P/C) < \log HR(T/C)$. This is easily seen from the diagram in Fig. 1.

From Fig. 1, it is clear that, in general, in an active control trial, one should not specify the margin δ to be an arbitrarily fixed number. In particular, one should avoid specifying a δ margin that is greater than the effect of the control. How can this be accomplished?

If the true hazard ratio, $HR(P/C)$, is known, then this can be done easily by defining the δ margin to be a fraction of the control effect, e.g., $\delta = 1/2 \log HR(P/C)$. However, the true control effect is never known even if there were a placebo present in the current trial. The true control effect can only be estimated. When there is a placebo in the current trial, then the true control effect may be estimated by $\log hr(P/C)$. When there is no placebo in the current trial, the true control effect needs to be estimated from historical data. In either case, one can only provide at best a probability statement regarding the likelihood of $\delta < \log HR(P/C)$. For example, if the true control effect, $\log HR(P/C)$, can be estimated from the historical data by the lower limit of the 95% confidence interval (CI) of the control effect, then the δ margin defined as a fixed number equal to half of this estimate of the control effect, i.e.,

$$\delta = 1/2 \{ [\log hr(P/C) - 1.96SE[\log hr(P/C)]] \} \quad (5)$$

provides a high probability that $\delta < \log HR(P/C)$. But here it is implicitly assumed that the historical control effect remains the same in the current trial setting. If this constancy assumption does not hold, then this probability may not be high either.

Fig. 1 Control effect, treatment effect, and margin δ

The test of the null hypothesis in Eq. 3 by $\tau_0(\delta)$, where δ is defined as in Eq. 5, has been called the two 95% CI-testing procedure. That is, the null hypothesis in Eq. 3 is rejected if

$$\log hr(T/C) + 1.96SE[\log hr(T/C)] < \frac{1}{2} \{ \log hr(P/C) - 1.96SE[\log hr(P/C)] \} \quad (6)$$

A somewhat similar two 90% CI-testing procedure has been used in thrombolytic trials (White^[13]).

Note that this δ in Eq. 5 is not truly a fixed number because it is defined in terms of an estimate of the control effect from the observed historical data. Thus, treating δ as a fixed number in the hypotheses in Eq. 3 is not exactly correct.

It is argued that although the two 95% CI-testing procedure offers a high probability that $\delta < \log HR(P/C)$, it may be extremely conservative because the true control effect, $\log HR(P/C)$, may be very much underestimated by the lower limit of the 95% CI of the control effect. But this argument is true only if the constancy assumption holds. An example given later will show that this may not be conservative enough when the constancy condition fails to hold.

On the other hand, using the point estimate, $hr(P/C)$, in the estimate of the true control effect may lead to a margin δ that is larger than the true control effect with relatively high probability. That is, if one defines

$$\delta = 1/2 \log hr(P/C) \quad (7)$$

This probability would be even higher when the constancy assumption does not hold. Testing the null hypothesis in Eq. 3 with the statistic $\tau_0(\delta)$, where δ is defined by Eq. 7, is equivalent to an asymmetric two CI-testing procedure where the control effect, $\log HR(P/C)$, is estimated by the point estimate, $\log hr(P/C)$, which can be thought of as the lower limit of the 0% CI of the control effect.

In the fixed margin method, the determination of the non-inferiority margin δ is based on the estimate of the historical control effect. Depending upon how this estimate is actually defined, the constancy assumption may or may not be assumed. Thus, for example, if the 95% confidence lower limit is used as the estimate of the control effect, then the constancy assumption is clearly not assumed and the historical control effect is actually discounted. If the point estimate is used, then the constancy assumption would be implicitly made and there would be no discounting of the historical control effect. The non-inferiority margin is then defined as half of this discounted historical control effect. Thus, implicitly through the way the control effect is estimated by the historical data, the fixed margin method assumes that the active control is effective in the current trial setting, and its effect size is estimated by a certain

degree of discount of the historical control effect. Thus, the choice of the non-inferiority margin δ in the fixed margin method as discussed above can be problematic, because it can be too liberal or too restrictive depending upon whether the historical control effect is assumed to hold true in the current trial setting or whether it is discounted by taking for example the 95% confidence lower limit of the estimate of the historical control effect.

Non-inferiority Hypotheses with Fraction of Control Effect to be Retained

From the above discussion, it is clear that for the margin δ to satisfy the condition that $\delta < \log \text{HR}(P/C)$ with high probability, one must define δ as a certain fraction, $0 < \phi_0 < 1$, of the control effect, $\log \text{HR}(P/C)$, which is unknown and needs to be estimated with data from historical placebo control trials. The idea of considering retention of a certain fraction of the control effect has been discussed in Hauck and Anderson,^[14] Holmgren,^[15] Koch and Tangen,^[16] and Rothmann et al.^[17] When the non-inferiority hypothesis is formulated in terms of a fraction of control effect to be retained, it provides a couple of advantages. First, with the specification of ϕ_0 , one does not need to pre-specify a δ margin. Secondly, the fraction of control effect to be retained can be specified according to the trial objective. For instance, if the current trial objective is to demonstrate that the new treatment is non-inferior to the active control, then the fraction specified should be closer to 1. If the current trial objective is to demonstrate that the new treatment is simply effective, then the fraction specified may be relatively smaller. Current practice often sets $\phi_0 = 0.5$.

The definition of the fraction, ϕ , of control effect retained by the new treatment is simply,

$$\phi = \frac{\log \text{HR}(P/C) - \log \text{HR}(T/C)}{\log \text{HR}(P/C)} \quad (8)$$

where the active control is assumed to be effective, i.e., $\log \text{HR}(P/C) > 0$, in the current trial. The non-inferiority hypotheses may be stated as follows.

$$H_0 : \phi \leq \phi_0 \quad \text{vs.} \quad H_a : \phi > \phi_0 \quad (9)$$

where ϕ_0 is the desired fraction of active control effect to be retained by the new treatment. Upon substituting the expression for ϕ in Eqs. 8 into 9 and after some algebra, the null and alternative hypotheses in Eq. 9 can be restated as,

$$\begin{aligned} H_0 : \log \text{HR}(T/C) &\geq (1 - \phi_0) \log \text{HR}(P/C) \quad \text{vs.} \\ H_a : \log \text{HR}(T/C) &< (1 - \phi_0) \log \text{HR}(P/C) \end{aligned} \quad (10)$$

The alternative hypothesis of interest in Eq. 10 can be interpreted as a desire to rule out a loss of more than

$(1 - \phi_0)$ of the control effect. The fraction ϕ_0 reflects, in a sense, the level of evidence one may demand of the new treatment. For example, when $\phi_0 = 1$, i.e., requiring 100% retention of the control effect, the hypotheses in Eq. 10 become the superiority hypotheses in Eq. 1. When $\phi_0 = 0$, i.e., requiring 0% retention of the control effect, the hypotheses in Eq. 10 become indirect comparisons to the reference “placebo.”

Comparing to Eq. 3, one may view the expression $(1 - \phi_0) \log \text{HR}(P/C)$ in Eq. 10 as the δ margin although, here, $(1 - \phi_0) \log \text{HR}(P/C)$ is not a pre-specified number. It involves the true control effect, $\log \text{HR}(P/C)$, which is unknown. In the two 95% CI-testing procedure, the expression $(1 - \phi_0) \log \text{HR}(P/C)$ in Eq. 10 is replaced by the estimate Eq. (Eq. 5), and the whole expression is considered as a fixed δ margin. In contrast to a superiority trial or a fixed margin method, in an active control non-inferiority trial, the hypotheses in Eq. 10 involve two parameters: the hazard ratios $\text{HR}(T/C)$ and $\text{HR}(P/C)$, as discussed in Chen et al.^[18]

Recognizing the fact that $\log \text{HR}(P/C)$ is an unknown parameter, the following statistic T is proposed for testing the null hypothesis in Eq. 10.

$$T = \frac{[\log \text{hr}(T/C)] - (1 - \phi_0)[\log \text{hr}(P/C)]}{\sqrt{\{SE^2[\log \text{hr}(T/C)] + SE^2[(1 - \phi_0) \log \text{hr}(P/C)]\}}} \quad (11)$$

T is claimed to be asymptotically normal and to have good convergence property^[6]. One then rejects H_0 at the one-sided 2.5% significance level if $T < -1.96$. The fraction retention approach of Rothmann et al.^[17] was applied in 2001 in the review and evaluation of the effectiveness of Xeloda in two active control studies FDA^[19] and also discussed in Rothmann et al.^[17] An application of this method can also be found in Wang et al.^[20] termed this approach the Synthesis Method, referring to the synthetic nature of the test statistic T in (Eq. 11), whereas Rothmann et al.^[17] called it the fraction retention method referring to the fraction retention hypothesis (Eq. 9), for which the linearized test statistic T was applied.

Since in an active control trial, there is no concurrent placebo, one cannot estimate the control effect, $\log \text{HR}(P/C)$, from the current trial. In Eq. 11, the estimate, $\log \text{hr}(P/C)$, needs to be estimated with data from historical placebo control trials. For this to be valid, one has to assume that the current control effect has not changed over time or, if it has changed, how much it has been reduced. For example, one may assume that the current control effect is a fraction, θ , of the historical control effect. Thus, in Eq. 11, one may include a fraction, θ , in front of the estimate of the control effect, $\log \text{hr}(P/C)$, which is based on the data from historical placebo control trials. However, in practice, information for such θ would be difficult to come by. The fraction retention method as proposed by Rothmann et al.^[17] assumes that the constancy assumption

holds. Thus, in the discussion below, we will assume that $\theta = 1$.

It should be noted that in Eq. 8, it is assumed that $\log HR(P/C) > 0$, that is, the Rothmann's fraction retention method assumes that the active control is effective. Furthermore, in the test statistic T in Eq. 11, the fraction of control effect lost, $(1 - \phi_0) \log HR(P/C)$, is unknown and is estimated by $(1 - \phi_0) \log hr(P/C)$ based on historical data. Thus, it also implicitly makes the constancy assumption without stating it. Moreover, the statistic T combines data from the current trial with historical data from other completed trials, and this raises question with regard to the validity of the statistical inference drawn based on the test of the hypotheses in Eq. 9 or Eq. 10 by T and causes difficulty in the interpretation of the result.

RELATIONSHIP BETWEEN THE FIXED δ -MARGIN HYPOTHESES AND FRACTION RETENTION HYPOTHESES

It should be noted that because the fraction retention approach uses the historical control data for the estimate of the control effect in its test statistic Eq. 11, whereas the fixed margin approach uses the historical control data in the specification of its non-inferiority margin, the two methods appear to be different at least in the manner in which the control effect is estimated. The former assumes the constancy assumption holds, whereas the latter discounts the historical control effect. However, one can cast these methods within the same fraction retention hypothesis framework given by Eq. 10 as described below. Within this same framework of fraction retention hypothesis Eq. 10, one can see that the liberalism or conservatism of these methods is easily seen from their corresponding test statistics used to test the fraction retention hypotheses give in Eq. 10. These test statistics differ simply in the standard errors used for their respective estimator, $\log hr(T/C) - (1 - \phi_0) \log hr(P/C)$. Note that all these methods are considering 50% retention of the control effect. Certainly, 50% retention is arbitrary and subjective, but one can use other threshold if appropriate.

The test of the fixed δ -margin null hypothesis in Eq. 3 using the statistics $\tau_0(\delta)$ with δ defined by Eq. 5 is equivalent to the two 95% CI-testing procedure (Eq. 6). It can easily be shown to be equivalent to using the following statistic t to test the fraction retention null hypothesis in Eq. 10:

$$t = \frac{\{\log hr(T/C) - (1 - \phi_0) \log hr(P/C)\}}{\sqrt{\{SE^2 \log hr(T/C)\} + \{SE^2 [(1 - \phi_0) \log hr(P/C)]\}}} \quad (12)$$

One rejects H_0 at the one-sided 2.5% significance level if $t < -1.96$. From the triangle inequality, one can easily deduce that

$$\begin{aligned} & \sqrt{\{SE^2 \log hr(T/C)\} + \{SE^2 [(1 - \phi_0) \log hr(P/C)]\}} \\ & \geq \sqrt{\{SE^2 \log hr(T/C) + SE^2 [(1 - \phi_0) \log hr(P/C)]\}} \end{aligned} \quad (13)$$

and hence, it follows that $T < t$, whenever the common numerator of both T and t , $\log hr(T/C) - (1 - \phi_0) \log hr(P/C)$, is negative. Therefore, the null hypothesis H_0 in Eq. 10 will be rejected by T whenever it is rejected by t at the same critical value, say, -1.96 . This implies that relative to testing the null hypothesis in Eq. 10, the statistic t is deflating the type I error.

The test of the fixed δ -margin null hypothesis in Eq. 3 using the statistic $\tau_0(\delta)$ with δ defined by Eq. 7 based on the point estimate, $\log hr(P/C)$, is a special case of an asymmetric two CI-testing procedure. It is easily seen to be equivalent to using the following statistic t^* to test the null hypothesis in Eq. 10:

$$t^* = \frac{\{\log hr(T/C) - (1 - \phi_0) \log hr(P/C)\}}{\sqrt{SE^2 \{\log hr(T/C)\}}} \quad (14)$$

Once again, note that $t^* < T < t$ whenever the common numerator of t^* , T and t , $\log hr(T/C) - (1 - \phi_0) \log hr(P/C)$ is negative. Thus, in testing the null hypothesis in Eq. 10 at the same critical value of -1.96 , the statistic t^* inflates the type I error. Thus, the statistic T protects against the conservatism of t and the liberalism of t^* relative to testing the fraction retention null hypothesis in Eq. 10. It is shown that for time-to-event endpoints, the statistic t^* deflates the type I error from 0.025 to as low as approximately 0.0028, while t^* can inflate the type I error to as much as 0.50.^[6]

On the other hand, it is of interest to point out that these test statistics can be shown to correspond conditionally to two asymmetric CI-testing procedures, where the control effect is estimated by the lower limit of a $100(1 - \gamma)\%$ CI, $0 < \gamma < 1$. The test statistic t^* corresponds to $\gamma = 1$, t corresponds to $\gamma = 0.05$, and T corresponds to some $\gamma = \gamma_T$, where $0.05 < \gamma_T < 1$ such that if ${}^c(1 - \gamma_T) < 1.96$ denote the critical value corresponding to γ_T , then

$$\begin{aligned} & SE[\log hr(T/C)] + ({}^c(1 - \gamma_T) / 1.96) SE[\log hr(P/C)] \\ & = \sqrt{SE^2 \left[\log hr \left(\frac{T}{C} \right) \right] + SE^2 \left[\log hr \left(\frac{P}{C} \right) \right]}. \end{aligned}$$

Although in general γ_T depends on the unknown standard error, $SE[\log hr(T/C)]$, but for time-to-event endpoints, such as survival, one may obtain an approximate estimate of γ_T at the design stage as shown in Ref. [6], because one can derive an approximate estimate of the unknown $SE[\log hr(T/C)]$ at the design stage and hence ${}^c(1 - \gamma_T)$, from which γ_T can be obtained. This will be illustrated in more detail in the later section on sample size determination. From this two CI-testing procedure perspective, one obtains an intuitive explanation as to why

the statistic T for testing the hypothesis in Eq. 3 protects against the conservatism of t and the liberalism of t^* , even though the fraction retention method does not quite fit into the two CI-testing procedure framework in general as indicated above except in the case for time-to-event endpoint.

This duality between the fraction retention hypothesis testing approach and the two CI-testing procedure approach exists because both approach uses the historical data to estimate the control effect, and this estimate is then used in either the test statistic or in the determination of the non-inferiority margin. It should be pointed out that all methods as discussed above actually use the same fraction retention level of 50%, and the control effect is estimated from historical data that came from studies that have been completed and known. If historical data is not available for the active control, then none of these methods would be applicable to an active control trial.

SOME REMARKS

Remark 1: As noted previously, for the same fraction retention level, the fixed margin method is considered to be more conservative than the fraction retention method when the constancy assumption holds. However, the constancy assumption often cannot be verified without a placebo in the current trial. Therefore, in the fixed margin approach, an ostensible reason to select a conservative estimate of the control effect size (e.g., using the lower limit of a 95% confidence interval) is to minimize the potential impact of a deviation from the constancy assumption that is assumed under the fraction retention method. Perhaps, what is not readily appreciated is the fact that in the fixed margin approach, simply using a conservative estimate of the control effect size may not totally avoid the impact of an actual deviation from the constancy assumption as illustrated in the following example.

Example: Consider a highly effective cancer treatment C for relapsed and refractory multiple myeloma patients. Based on two randomized historical trials, a pooled point estimate of the response rate for treatment A is approximately 40% with an associated 95% confidence interval of (36–45%). A non-inferiority trial is proposed to demonstrate that a new treatment T is non-inferior to the control treatment C. The non-inferiority margin was selected based on the lower limit of the 95% confidence interval of 36% in the response rate. Clinically, it is believed that the treatment effect in response rate can be compromised at most 40% in a non-inferiority trial (i.e., a 60% retention of the control effect). Based on the fixed margin method, the non-inferiority margin is determined to be $\delta = (1 - 0.60) \times 36\% = 14.4\%$. The non-inferiority hypothesis using this margin may be considered conservative according to current regulatory guidance. However, if the constancy assumption does not hold in this case, and the response rate

in the current non-inferiority trial is actually 25% say due to patient population differences and/or some other reasons, the non-inferiority margin of 14.4% would be quite large compared to the current control effect of 25%.

Remark 2: As noted earlier, the fraction retention threshold ϕ_0 determines the stringency of the non-inferiority margin, and in turn it will affect the sample size required for the non-inferiority trial. An important question regarding how stringent should the fraction retention threshold be for a given non-inferiority trial has never been resolved. It has been argued that the FDA drug regulations do not require that a new treatment has to be shown to be non-inferior to an active control in order to be approved. All that the regulations require is that the new treatment be superior to placebo. If that is the case, then what fraction retention threshold would be acceptable as a demonstration of superiority to a placebo that is not present? From an ethical perspective, for a trial with mortality or serious morbidity outcome, it would be unacceptable to treat patients with a potentially inferior new treatment, unless this new treatment is expected to provide some other substantive benefit that may offset such inferiority. However, the problem is that these potential benefits are yet to be demonstrated and quantified, and hence cannot be used in the actual determination of the non-inferiority margin, although they certainly may be considered in the final benefit/risk assessment. This raises the questions as to how liberal or strict should the fraction retention threshold be and how does one determine that?

Remark 3: The definition of the fraction, ϕ , of control effect to be retained by the new treatment can also be stated in terms of hazard ratios as follows.

$$\phi_h = \frac{HR(P/C) - HR(T/C)}{HR(P/C) - 1} \quad (15)$$

where the active control is assumed to be effective, i.e., $HR(P/C) - 1 > 0$, in the current trial. The non-inferiority hypotheses may be stated as follows.

$$H_0 : \phi_h \leq \phi_0 \quad \text{vs.} \quad H_a : \phi_h > \phi_0 \quad (16)$$

where ϕ_0 is the desired fraction of active control effect to be retained by the new treatment. Upon substituting the expression for ϕ_h in Eq. 15 into 16, and after some algebra, the null and alternative hypotheses in Eq. 16 can be restated as

$$\begin{aligned} H_0 : HR(T/C) &\geq 1 + (1 - \phi_0)[HR(P/C) - 1] \quad \text{vs.} \\ H_a : HR(T/C) &< 1 + (1 - \phi_0)[HR(P/C) - 1] \end{aligned} \quad (17)$$

When $0 < \phi < 1$, it can be shown easily that $\phi < \phi_h < 1$. Thus, if the non-inferiority null hypothesis in Eq. 10 is rejected, then it follows that the null hypothesis in Eq. 16 is rejected for the same value of ϕ_0 . Also, a test statistic

for those hypotheses in Eq. 16 analogous to Eq. 14 can be constructed. An application of such a test statistic can be found in Ref. [19].

To pose the non-inferiority hypothesis in Eq. 16 directly in terms of the hazard ratios is attractive in that it offers ease of interpretation. Wang et al.^[21] have proposed a ratio test statistic for testing the non-inferiority hypothesis in Eq. 16. However, unlike the authors' claim that it has greater power when compared to the linearized version, its power is comparable to the Rothmann's linearized test statistic for the hypothesis in Eq. 10. The reason is that the authors assumed equal variance under the null and alternative hypotheses in the derivation. However, when one allows unequal variance as is likely to be the case, the power is substantially reduced.

PLANNING FOR AN ACTIVE CONTROL TRIAL

The following are some important issues to be considered when contemplating an active control trial. See also the articles by Hung et al.^[8–10]

Validity of Active Control Trials

In order to have a valid statistical inference for an active control trial, several key assumptions have to be reasonably satisfied. The first assumption is that in the current trial setting, the active control is effective. Generally, this assumption is unverifiable. If this assumption is not true, then, for a superiority trial, one may only conclude that the new treatment is effective, but not that it is superior to the control. For a non-inferiority trial, this assumption may lead to the approval of a new treatment that is actually worse than a placebo. If possible, one should consider special design features and other concurrent trials that may provide evidence that the active control is effective. The second assumption is that the current trial has assay sensitivity. Assay sensitivity is defined as the ability of a trial to show an effective treatment to be effective. The ICH-E10 document on the Choice of Control^[3] introduces and discusses this concept in some detail. It essentially involves the quality of a trial including various aspects of trial design, conduct, and analysis. The third assumption is that the control effect in the current trial is either the same as or is some fraction of the historical control effect, and that there are placebo control historical trials on the basis of which the control effect and its variability can be reasonably assessed. In this regard, issues regarding quality, reliability, publication, and selection biases of these historical trials are of major concern and need to be dealt with. One should strive to make the current trial as similar as possible to the historical trials. If the active control effect has been diminished, then one needs to be able to specify the amount of reduction. The fourth assumption is that the trial is free of bias. An active control trial has potential

for bias toward the null without unblinding the trial. Strict standard operating procedures should be in place. As none of these assumptions can be truly verified, the validity of an active control trial is always subject to question.

The fraction retention method may have further validity issue as its test statistic is based on integrating data from the current trial with the data from some completed known historical control data. On the other hand, the fixed margin method tends to be conservative when the constancy assumption holds. However, when this assumption does not hold, then it is difficult to judge whether the specified margin would be liberal or conservative. For both methods, the actual fraction of the control effect to be retained has customarily been set at one-half. This retention level is arbitrary, and for a given situation, other levels may be appropriate and should be considered.

Therefore, in view of these issues, active control trials should be considered only when using a placebo would truly be unethical.

SOME DESIGN CONSIDERATIONS

As there is no placebo in the current active control trial, the control effect needs to be estimated from historical trial data. The questions one should address are as follows: What historical placebo control trials are available? Which collection of historical trials will be used to provide the estimate of the control effect? What kind of analysis will be used to provide this estimate? How reliable is the estimate of the historical control effect?

Although the control effect may be assessed by using data from historical randomized placebo-controlled studies, the current control effect may be different because of changes in patient population, standard care, medical practice, etc. One should design the current trial to be as similar as possible to the historical placebo control trials used in estimating the historical control effect. Important factors that may influence the trial outcome should be identified and may include region, gender, ethnicity, and patient characteristics. Standard of care differences may affect trial outcome. The current trial should also be as similar as possible to the historical trials with respect to these factors. Some adjustment of the historical control effect may be necessary by either replacing the control effect, $\log HR(P/C)$, in the hypotheses in Eq. 10 by $\theta \log HR(P/C)$, where $0 < \theta < 1$, or by adjusting using a mathematical model for population and study differences.

One should be clear about the primary objective of the active control trial. Should the objective be to demonstrate superiority of the new treatment to the control, non-inferiority to the control, or simply effectiveness of the new treatment? Each of these objectives requires a hypothesis with a different degree of tightness in the margin. For demonstration of non-inferiority, one needs to specify a fraction, ϕ_0 , of the control effect to be retained.

The specification of this fraction depends on the trial objective. If the active control is highly effective, then there may be no legitimate reason to consider a new treatment that is inferior to this control. In this case, one may require φ_0 to be closer to 1. However, if the new treatment offers some important benefits that are not available from the active control, such as a better toxicity profile, then φ_0 may be specified somewhat smaller. In the latter case, one may only conclude that the new treatment is effective, but not non-inferior to the control. The actual value of φ_0 may also depend not only on types of therapies, diseases, and endpoints but also on the distributional properties of the estimated control effect as well.

The conservatism of the two 95% CI-testing procedure does not take into account any of the concerns regarding the validity of the active control trial, nor the confidence one has regarding the estimate of the control effect. At the design stage of an active control trial, such concerns and lack of confidence may be reflected in the values specified for various design parameters. The design parameters include the fraction, φ_0 , of control effect to be retained and the fraction, θ , of the historical control effect to be reduced. The specification of these design parameters should also take into consideration how the control effect estimate is calculated and the resultant sample size requirement. Once φ_0 and θ have been specified, one can calculate the sample size required for testing the non-inferiority null hypothesis in Eq. 10.

SAMPLE SIZE DETERMINATION

The sample size required for testing the null hypothesis in Eq. 10 at a given significance level can be calculated as follows. The calculation depends on an appropriate assessment of the control effect. As mentioned before, using the statistic T to test the null hypothesis in Eq. 10 is conditionally equivalent to an asymmetric two CI-testing procedure, where the control effect is estimated by the lower limit of a $100(1 - \gamma_T)\%$ CI. The value of this γ_T is not known ahead of time. However, for time to event endpoint, this γ_T can be approximately calculated at design stage based on the pre-specified number of events at stopping time (the final analysis) and the significance level used in the test of the null hypothesis in Eq. 10.

In practice, the control effect sometimes cannot be assessed reliably either because there is insufficient historical data or the control effect may have changed over time. In such cases, the sample size calculation should be based on a conservatively estimated control effect, e.g., using the lower limit of the 95% or even 99% CI.

In oncology, we require, as stopping rules for time to event endpoints, pre-specified fixed number of events. A lower bound and approximation for the asymptotic standard error of $\log hr(T/C)$ for a 1:1 randomization is given by $2/\sqrt{n}$, where n denotes the pre-specified total number

Table 1 Number of Events Needed for 80% Power

HR(T/C)	Number of events	Cutoff
1	4801	1.0842
0.95	1505	1.0976
0.90	750	1.1044
0.85	446	1.1085
0.80	291	1.1114

of events at stopping. The use of this lower bound for the standard error at the design stage allows us to algebraically “equate” the use of a test statistic with a pre-specified two CI procedure.

Consider the case where $\alpha = 0.025$, $\beta = 0.2$, $\varphi_0 = 0.5$, $\theta = 1$, $\log hr(P/C) = 0.234$, and $SE[\log hr(P/C)] = 0.075$. Table 1 gives the number of events needed for various “alternatives” for $HR(T/C)$ and the corresponding non-inferiority cutoffs for the upper limit of the 95% CI for $\log HR(T/C)$. The cutoff is defined as $\delta = (1 - \varphi_0)\{\log hr(P/C) - c_{(1-\gamma)}SE[\log hr(P/C)]\}$, where $c_{(1-\gamma)}$ is the solution to the equation,

$$\begin{aligned} & 2/\sqrt{n} + c_{(1-\gamma)}(1 - \varphi_0)SE[\log hr(P/C)]/1.96 \\ & = \sqrt{\{4/n + (1 - \varphi_0)^2 SE^2[\log hr(P/C)]\}}, \end{aligned}$$

and the number of events needed at stopping is given by n where n solves

$$\begin{aligned} \frac{2\Phi^{-1}(1 - \beta)}{\sqrt{n}} &= (1 - \varphi_0)\log hr(P/C) - \log hr(T/C) \\ &+ \Phi^{-1}(\alpha)\sqrt{\{4/n + (1 - \varphi_0)^2 SE^2[\log hr(P/C)]\}}. \end{aligned}$$

CONCLUSION

In the design of a non-inferiority trial, if one believes that the historical active control effect is likely to be maintained in the current trial setting, then the hypothesis with a retention of certain fraction of the control effect could be a reasonable formulation, although as noted earlier a basic problem with this approach is inherent in the test statistic used to test the non-inferiority hypothesis that is partly based on data from past completed studies (if they exist). If there is reason to believe that the historical control effect has been reduced over time, then the fixed margin approach would be more appropriate, although it remains a challenge to provide a reasonable estimate of the current control effect. If the control effect in the current setting is greater than the estimate, then the margin would be conservative. On the other hand, if the control effect in the current setting is smaller than the estimate, then the margin would be liberal as illustrated by the earlier example. In either the fraction retention or the fixed margin

approach, there is a basic lack of a reference for assessing whether a given margin is too liberal or too restrictive. Further research in this regard would be needed in order to develop a more acceptable approach to the design of a non-inferiority study.

Active control non-inferiority trials should be considered on a case-by-case basis. We need to have assurance that the active control effect exists in the current study patient population. It is recommended that the best available treatment be used as the control. We need to assess whether the current effect size, if it exists, has diminished. We should have historical randomized placebo-controlled studies that can provide reliable estimate of the historical control effect. The current trial population should be as similar as possible to the populations studied in the historical control studies. A “non-inferiority” trial may be prone to bias toward “no difference.” Careful attention should be paid to the conduct and analysis of such a study. It should be well monitored and conducted. After the study is done and all efficacy and safety data collected, the evidence as to whether the new treatment is effective should be carefully examined. One should then assess this evidence by incorporating any other additional substantive benefits that the new treatment can provide to the patients that the control cannot. In view of the subjective nature of the margin determination, it is recommended that in the final efficacy assessment, the pre-specified non-inferiority margin should serve more as a guide than as an absolute cutpoint. The final conclusion of course should still follow the usual benefit/risk assessment.

Abstract

This entry discusses the simulation in early phases of clinical trials, specifically through oncology dose-escalation trials to discuss some theoretical and practical issues in trial simulations.

Keywords: Active control studies; Noninferiority; Preservation.

INTRODUCTION

Noninferiority analysis for comparing a new experimental therapy with a selected active (or positive) control therapy is a difficult and often very controversial subject,^[1–17] particularly when the active controlled clinical trial does not include a placebo arm. In approximately late 1970s to early 1980s, the concept of noninferiority was generally defined using a one-sided hypothesis with a prespecified noninferiority margin (e.g., Ref. [18]). The aim of the noninferiority analysis is to demonstrate that the experimental therapy is not inferior to the active control treatment within the margin with respect to the efficacy endpoint(s) of main interest. Hypothesis testing or confidence interval approach was frequently employed. In late 1980s to mid-1990s, noninferiority was sometimes considered as two-sided therapeutic equivalence, mostly seen in cancer treatment trials, with a prespecified equivalence range. Indeed, for some time, it was not clear as to whether the real interest in a noninferiority clinical trial is that the new treatment is not much different in effect from the active control or that the new treatment is not much less effective than the active control. The terms equivalence and noninferiority were often used interchangeably for a little while in the mid-1990s. Then, some literature in 1997–2001—the points to consider of the Committee for Proprietary Medicinal Products (CPMP) document¹¹ from the European regulatory agency, and the discussions in the Food and Drug Administration (FDA)—made the distinction between equivalence

and noninferiority. Intuitively, noninferiority can be viewed as one-sided equivalence. Historically, growing awareness and regulatory attention to noninferiority and equivalence analysis appeared to begin around the 1980s.

Difficulty in defining a noninferiority margin has probably been overlooked for a long time. The noninferiority margin is tied to the clinically important difference that one hopes to rule out between the experimental and the control treatments. Hence the margin determination cannot be based solely on some kind of statistical criteria. It is generally a collective effort that consider many factors, such as, the effect of the active control, dosages of the active control agent and/or concomitant medication, background medications, etc. International Conference on Harmonization (ICH)-E9⁸ states that the margin is the largest difference that can be judged as being clinically acceptable and should be smaller than the differences observed in superiority trials of the active comparator. ICH-E10⁹ states that the margin chosen for a noninferiority trial cannot be greater than the smallest effect size that the active drug would be reliably expected to have compared with placebo in the setting of the planned trial. These are general principles. None of these documents discuss how to define a margin or how to analyze a noninferiority study.

OBJECTIVES OF NONINFERIORITY TRIAL

Two main objectives regarding the effectiveness of an experimental therapy are often considered in a noninferiority trial. One objective is to establish evidence for the efficacy of the experimental treatment, a regulatory requirement for

The views expressed in this article do not necessarily represent those of the U.S. Food and Drug Administration.

drug approval. The direct comparison of the experimental treatment with the active control together with historical evidence on the active control is often needed to lead to the assertion that the experimental treatment would have been more effective than placebo had the placebo been included in the noninferiority trial. Pursuance of this objective is the focus of many articles, e.g., Refs. [19,20]. The other objective is to assert that the experimental treatment is not much less effective than the control treatment by a noninferiority margin. This renders a direct assessment of the performance of the experimental treatment relative to the active control treatment, which is guarded by the noninferiority margin, e.g., Ref. [10]. The two objectives are interrelated. The former objective is usually a prerequisite consideration when pursuing the latter objective. Undoubtedly, the latter objective is a higher bar to achieve.

In many practices, when setting the noninferiority margin, one criterion often taken into consideration is that the experimental treatment retains at least some portion of the control effect. In effect, demonstration of the percent effect preservation may also be a goal for the noninferiority analysis. A well-known case example is retention of at least 50% effect for approving a new thrombolytic agent in noninferiority trials, which is considered by the Center of Biologics Evaluation and Research (CBER), FDA, as described in Ref. [10]. Other percentages of retention are certainly possible, depending on many factors such as diseases, drug safety profile, cost consideration, the confidence about the estimated control effect, etc. In fact, preservation of some fraction of the control effect is an important consideration to ensure that the efficacy of the experimental therapy relative to the unavailable concurrent placebo can be established with great confidence. In some cases, it may be sufficient to quantify how much risk that it would be the worst case is acceptable or to ensure that the amount of therapeutic effect lost by the experimental treatment is maximally allowable. However, the concept of “not inferior” cannot always be defined quantitatively only by a retention of some fraction of the control effect, see Ref. [21].

STATISTICAL METHODS OF NONINFERIORITY ANALYSIS

Literature provides two major classes of statistical methods for entertaining the objectives in noninferiority analysis. Use of confidence interval has been a common practice for decades, as found in such works as Fleming,^[2] CBER/FDA,^[10] and Blackwelder.^[18] First, one calculates a 95% confidence interval for the effect of the experimental treatment relative to the active control comparator from the active-controlled trial. If the entire confidence interval falls in the noninferiority range referenced by the noninferiority margin, then an argument for noninferiority defined on the basis of the prescribed margin can

be made. By asserting that the experimental treatment is not substantially less effective than the control, one can then indirectly infer that the experimental treatment is efficacious (relative to the putative placebo) or preserves the targeted percent of the control effect. As an example, in the case study of Fleming,^[2] mitoxantrone (MITX, an experimental treatment) was compared to doxorubicin (ADR, a widely considered standard of care) in treatment of advanced breast cancer on survival. Fleming pointed out that using the conventional 5% level of significance in the no treatment placebo controlled study and a reliable estimate of the active control effect on survival, in principle, survival with MITX relative to ADR can be represented by positioning ADR at 100% and no treatment at 80%. Survival on MITX was estimated to be 81% as long as that on ADR with 95% confidence interval of 58%–112% from an active control study. Because the lower bound of this confidence interval does not exceed 80%, the active control study failed to provide sufficient statistical evidence to assert that MITX gives greater survival than no treatment. The confidence interval analysis can be easily transformed to hypothesis testing with the same defined margin.^[18]

In the confidence interval approach, the noninferiority margin is the criterion for the determination of a noninferior experimental therapy as compared with a control therapy. Thus, the confidence interval method necessitates prespecification of the noninferiority margin. It is usually a very challenging task to quantitatively set the noninferiority margin for defining the concept of “not inferior” and at the same time indicating “not much less effective.” Consideration must include the efficacy of the experimental treatment, side effects, cost, convenience of administration, the effect of the active control including its size, the variability, and its consistency among the historical trials. For the traditional confidence interval method, once this margin is determined, it is treated as a fixed number without variability in the statistical inference for the active control trial.

The other class of statistical methods for noninferiority analysis may be collectively called synthesis method, such as those found in Refs. [19–26]. This type of methods implement a formal framework for cross trial statistical inference. Under such framework, the method synthesizes the estimated relative effect of the experimental treatment vs. the control from the active controlled trial and the estimated effect of the control treatment relative to placebo from historical evidence. The synthetic estimate results in a test statistic for formally testing the efficacy of the experimental treatment relative to a putative placebo and is used to estimate the fraction of the control effect that may have been preserved by the experimental treatment had the placebo been included in the active controlled trial. In the statistical hypothesis of percent effect preservation, the noninferiority margin is an explicit function of the control effect. If the control effect can be precisely

ascertained, a null percent of effect retention by the experimental treatment implies that it is more effective than the putative placebo and 100% preservation implies that the experimental treatment is more effective than the active control. In contrast to the confidence interval method, the synthesis method does not require the full pre-specification of the noninferiority margin in the hypothesis but needs only to set the level of percent for preservation. The statistical uncertainty in the effect of the active control is incorporated as a part of statistical inference with the synthesis method.

Simon^[27] introduced a Bayesian method that perhaps incorporates the concept of synthesization more naturally. Under this framework, the value of the expected placebo event rate is allowed to vary from past to present, from population to population, or from trial to trial. So are the effect of the active control and the effect of the new treatment relative to placebo. All these parameters are assumed to follow some statistical distributions identified by a number of hyperparameters that quantify central tendency and spread or scale. Using the data from historical trials and the active controlled trial and the given prior distributions, one can compute the posterior probability that the experimental treatment is effective relative to placebo or the probability that the experimental treatment retains at least some percent of the control effect. Statistical inference is then drawn on the basis of the posterior probability. It is worth noting that with noninformative priors on the placebo effect and the effect of the experimental treatment relative to the placebo, Simon's method renders essentially the same conclusion as the frequentist synthesis method gives.

Recently, Wang and Blume^[28] have considered a likelihood-based approach to define the noninferiority margin based on the support intervals from historical trials and to assess the strength of evidence for noninferiority under a pre-specified fixed margin.

CHALLENGES

Despite the fact that there has been considerable experience in noninferiority analysis, many difficulties and controversies remain. One of the difficult issues concerns choice of the active control. Usually, the selected active control for noninferiority trial must be effective that has been demonstrated in historical evidence. This is a part of the "assay sensitivity" issue discussed in great length in the ICH E-10 document.^[9] After an active control is selected, how to estimate the effect of the active control and which historical trials should be selected for estimation is also difficult. For the noninferiority analysis, improper handling of noncompliant patients might induce a bias that makes it easier to show no difference between the treatments. The analysis of the intent-to-treat population preserving randomization might not be conservative for noninferiority analysis

as generally thought in showing treatment differences in a superiority analysis. There are abundant resources in literature to enlighten many of such difficult issues.^[11-17]

Several other fundamental issues, however, have been rarely addressed in practical applications of noninferiority analysis, as stipulated in Ref. [29,30]. The main study objective is often not entirely clear in designing a noninferiority clinical trial. If the objective is showing that the experimental treatment is not considerably less effective than the active control, then the margin needs to be defined a priori and cross trial inference is not always necessary. The margin selection cannot be based purely on some statistical criteria and clinical consideration plays a vital role. Many approaches have been articulated, e.g., Refs. [31]. On the other hand, for showing that the experimental treatment is effective relative to a placebo or preserves some fraction of the control effect, cross trial inference cannot be avoided (see, e.g., Refs. [19-26,29,30-33]).

The value of the control effect is almost always unknown in both the active control trial population and the relevant historical trial populations. In the active control trial, the effect of the active control is not estimable. The historical trials provide an estimate for the control effect. This estimate may be applicable to the active control trial when the effect of control in the historical trial populations carries to the active control trial population, the so-called constancy condition. This condition implies that the active control trial and historical trial patient populations are similar, that trial design, background medications, etc. are similar, and that the control effect does not change over time or because of any other factors. Noninferiority analysis that requires cross trial statistical inference is extremely difficult because of the following reasons: (i) the constancy condition cannot be verified because of unavailable concurrent placebo in the noninferiority trial; (ii) trial-to-trial heterogeneity is mostly present in practice. In fact, when the constancy condition is in doubt, no straightforward statistical or clinical means can be used to properly adjust the bias and/or the variability, and no statistical method can render a conclusion that is defensible under the conventionally required criteria for statistical evidence in clinical trials. Placebo creep is often of concern if the control effect changes over time (see, e.g., Refs. [23,34]). It is therefore critical to assess the potential violation of the constancy assumption (Refs. [34]).

Even if the constancy condition holds, the fact that the effect of the active control is at best estimable from historical data presents a great challenge to the conventional framework of statistical inference. To conclude via noninferiority testing that the experimental treatment would have been effective compared to a placebo had the placebo been studied, cross trial inference is necessary. What is the probability of type I error pertaining to falsely making such a conclusion in the cross trial statistical inference? If the type I error probability cannot be defined, the *p*-value that is routinely used for quantification of statistical evidence

in placebo controlled clinical trials becomes meaningless. This issue also arises in testing for percent effect retention. Even with classical confidence interval approach, when the noninferiority margin involves the estimated control effect, the statistical uncertainty of the estimated margin in principle arguably needs to be incorporated in evaluation of the type I error of making a false assertion of noninferiority. This cross trial type I error probability has recently been considered by many researchers, e.g., Refs. [19–26,29,30,34]. Nevertheless, the relevance of this error probability would continue to be debated for the days to come.

If the constancy assumption is very much in doubt, the type I error probability, however it is defined, may be irrelevant. There is no way to know the worst difference in the control effect between the active controlled trial population and the historical trial populations without truly knowing the population similarities and whether the constancy assumption holds. The cross trial type I error probability may not be controllable in both confidence interval method and synthesis method. In this case, the noninferiority analysis must be avoided unless an extremely conservative margin can be defined so that the result of the analysis may be interpretable with a very small chance of drawing a false conclusion. However, as argued in Refs. [29,30], such a risk is beyond the traditional alpha error and is not statistically quantifiable.

CONCLUSION

Difficult and complex as it is with either limited or rich relevant historical information, a noninferiority active controlled trial design is not always informative for studying a new treatment. Interpretability of the results of a noninferiority trial depends on its study objective(s), how robust is the control effect estimated from the historical placebo controlled trials, whether this control effect is applicable to the targeted patient population, and many other factors. Cross-trial inference is almost unavoidable whether it is implicitly or explicitly made.

Abstract

For the past few decades, there has been considerable interest among pharmaceutical and other medical product developers in adaptive design clinical trials, in which knowledge learned from data of an ongoing trial affects design features or analysis of the study. Following the initial release of the FDA Draft Guidance “Adaptive Design Clinical Trials for Drugs and Biologics” in early 2010, there have been high expectations of an increase in regulatory submissions involving adaptive design features, particularly for trials that are intended to provide substantial evidence for product registration. More recently, the finalized FDA Guidance on Adaptive Designs for Medical Device Clinical Studies lays out the principles of conducting adaptive design clinical trials. The passed 21st Century Cures Act encourages a broader use of adaptive design in clinical studies. Despite all these, there remain some concerns and questions regarding statistical analyses and operational challenges in conducting adaptive design clinical trials. In this article, we provide some case studies reviewed at the FDA and general considerations for developing proposals for adaptive design clinical trials.

Keywords: Adaptive design; Adaptive seamless design; Critical path initiative; Food and Drug Administration; Operational bias; Study integrity; Type I error rate.

INTRODUCTION

To support regulatory standards for evidence in a medical product application, statistical inferences in larger scale trials are generally performed. One of the critical issues is whether results generated from the trials are interpretable with respect to the safety and effectiveness of the proposed medical product in the seeking indication. It is recognized that medical product development has become increasingly challenging, inefficient, and costly. The United States Food and Drug Administration’s (FDA) critical path initiative document^[1,2] had called for the need for more scientific efforts and efficient evaluation tools used in product development. Adaptive trial design was one of the topics focused on in the medical utility area. Additionally, the recently passed 21st Century Cures Act encourages a broader use of adaptive design in clinical studies, so a beneficial treatment can be made available sooner for patients in need.

Adaptive designs have been commonly used in clinical trials to advance medical research for many years.

An adaptive clinical trial design is one where data collected during the trial are monitored and analyzed in order to make modifications to the trial as it continues. For a clinical trial with an adaptive design, interim analyses are needed. Because of the usage of interim data for study modification, such designs have been thought by many to speed up the development process of investigational products and maximize the chance of trial success. Therefore, adaptive designs have been attractive to industry researchers who are looking to reduce costs and streamline the product development process. Additionally, there are potential ethical advantages of adaptive designs with respect to both efficacy and safety. For examples, adaptive design may help to protect patients from harm if interim results show a clear detrimental tendency of the investigational therapy, or adaptive design may lead to earlier availability of an effective treatment with exposure of fewer patients in the testing process.

Despite enthusiasm, the use of adaptive design in product development may or may not be appropriate depending upon a number of factors. Factors likely to determine a choice of an adaptive approach could include what is known at the planning stage, for example, objectives and target populations, accrual rate, choice of endpoints, characteristics of the investigational products, and others.

Note: The views expressed are those of the authors and do not represent the official position of the US Food and Drug Administration.

The potential advantages and disadvantages of an adaptive design over a traditional design at the study planning stage, especially for trials that are intended to provide substantial evidence for product registration, should be carefully assessed. Furthermore, all considerations should be evaluated whether simple and conventional adaptive designs, such as group sequential designs, will suffice to establish safety and efficacy of a product. On the contrary, complex adaptive designs may not be cost- or time-efficient as detailed design justification and possibly extensive simulation studies would usually be needed. This process can significantly delay the initiation of a trial. In general, an adaptive design with a way-too-early interim look may not be useful because there is too little information and it is subject to large variation to properly adapt the trial. Studies that stop too early for success may have inadequate safety data accrued, and both safety and efficacy are considerations for a premarket approval application. In addition, having sufficient sample size to assess secondary endpoints may need to be taken into consideration when planning an early study termination for efficacy, particularly if the secondary endpoint has less frequency (e.g., mortality).

Many adaptive design features have been proposed in the literature and/or have applied to clinical trials, including adaptive dose escalation, adaptive randomization, adaptive dose finding, and sample size re-estimation (SSR). However, modifications of an ongoing trial that is intended to provide substantial evidence for product registration, on the one hand, have been viewed by some as a contradiction to the confirmatory nature in the product development process. On the other hand, such modifications may be necessary for the well-being of patients. As a result, for many adaptive design clinical trials, there are outstanding statistical and operational issues that can affect the interpretability and validity of trial results. FDA Draft Guidance for drugs and biologics^[3]—“Adaptive Design Clinical Trials for Drugs and Biologics”—and final Guidance for medical devices^[4]—“Adaptive Designs for Medical Device Clinical Studies”—state explicitly that all planned adaptations should be prespecified at the design stage, and post hoc modification of study features is not considered to be an adaptive design. While both Guidance documents encouraged exploring the use of adaptive designs in early stage studies, their emphasis was on those studies that are intended to provide primary evidence for product registration. There are three major concerns associated with adaptive design clinical trials emphasized in the Guidance: (1) control of the study-wise type I error rate, (2) minimization of the impact of any adaptation-associated statistical or operational bias on the estimates of treatment effects, and (3) the interpretability of study results. These concerns are expected to be addressed during the design and study protocol stage when an adaptive design clinical trial is planned for a regulatory submission.

For the past few decades, adaptive design clinical trials have been proposed and conducted in regulatory

submissions. The proposed adaptive design features differ from one therapeutic area to another. FDA’s experiences in adaptive design have been in the review of proposals at the investigational new drug and investigational device exemption stages, as well as premarket applications. Some of the products have been approved based on results generated from adaptive design clinical trials. The following gives a brief summary of possible types of adaptive designs:

- **SSR:**
The sample size planned originally may not be sufficient. This could attribute to incorrect assumptions or variation greater than expected in the current ongoing trial.
- **Change of study objective:**
The superiority objective originally planned may be too ambitious after interim results are available, or vice versa, that the benefit of the investigational product based on interim results turns out to be greater than expected.
- **Change of the primary endpoint:**
The primary endpoint was chosen inappropriately at the planning stage. For example, the choice of components in a composite endpoint may be suboptimal.
- **Termination/modification of treatment arms:**
Interim results may suggest that some treatment arms are not efficacious or harmful and therefore should be dropped from the study, or treatment arms or dosing schedule is not optimal and should be modified.
- **Change of statistical methods:**
Interim results may suggest that more optimal statistical methods could be chosen for the primary analysis. For example, the distribution of some baseline covariates is different between groups, and therefore, analysis of covariance or propensity score method is more appropriate than the originally planned *t*-test.
- **Change of study population:**
Results from interim analyses may suggest the benefits of a subgroup, or may want to expand the inclusion criteria because of slow patient recruitment.
- **Adaptive seamless design:**
An adaptive seamless Phase 2/3 design in drugs and biologics is a two-stage design consisting of a learning stage and a confirmatory stage where data from both stages are combined for a final analysis. Such two-stage design clinical studies can apply to medical device submissions as well, whereas the terminology of Phase 2/3 is not used. Trials of this type are reviewed rigorously as Phase 3 trials or trials that are intended to provide substantial evidence for product registration in regulatory submissions. There are also operationally seamless but inferentially distinct Phase 2/3 studies, in which two traditional trials (Phase 2 and Phase 3) are conducted under a single study protocol but analyzed separately. For this type of trials, the control of type I error rate in the Phase 3 part is expected, which is the

same as Phase 3 trials intended to provide substantial evidence for regulatory approval of products. It should be noted that the terms “seamless” and “Phase 2/3” were not used in the FDA Draft Guidance for drugs and biologics as they have sometimes been adopted to describe various design features.

The layout of the article is as follows: Issues and considerations regarding the above referred design adaptations are discussed. Case studies are provided to illustrate the issues associated with study adaptations. The article ends with concluding remarks. The discussion in this article focuses on trials that are intended to provide substantial evidence for product registration.

ISSUES AND CONSIDERATIONS ON DESIGN ADAPTATION

The following provides issues and considerations for each possible type of study adaptation.

1. SSR:

SSR is a design adaptation that occurs most frequently in regulatory submissions just after group sequential design. In general, SSR based on blinded interim analyses of aggregate/overall data is considered not to be problematic, as these approaches have very limited potential to introduce bias or impair the validity and interpretability of study results. SSR based on unblinded knowledge of interim treatment effects, however, can raise issues related to type I error inflation and/or operational biases introduction, and has to be approached with greater caution. In planning any unblinded SSRs in regulatory submissions, clear analytical derivations or statistical justifications to demonstrate a control of type I error rate are expected, as well as strategies/plans to mitigate operational bias at the design stage. For example, reviewers at the Center for Biologics Evaluation and Research (CBER) in the FDA have agreed to multiple proposals using the conditional power approach.^[5] One caveat about SSRs is that the approaches can lead to changing the minimum effect size for which a statistically significant result will occur. Such a statistically significant result, however, may be no longer clinically meaningful. Therefore, decision rules with respect to sample size increase to ensure that statistically significant results are also clinically meaningful should be clearly prespecified. In addition, the timing of an SSR should be factored into the plan. An early SSR (e.g., 20% of information) may result in an unreliable new sample size because of limited accrued data that are subject to large variation, whereas a late SSR (e.g., 80% information) may be pointless as the initial planned accrual may already be completed by

this time. Simulations may be explored to determine the optimal timing for interim analyses for SSRs under different scenarios. Similar with any adaptive approaches, the timing and the rules for any SSRs should be clearly prespecified in the study protocol. For trials with multiple SSRs, it raises a serious concern that data generated from the study fluctuate and that the effect of the proposed product may not be understood to a degree of conducting trials that aim to provide substantial evidence for product registration. Studies aiming for exploratory purposes are usually performed to investigate unknowns about the product in this situation.

2. Termination or/and selection of treatment/dose arms

In many drugs and biologic product developments, there may be still some doubts about the optimal dose of the experimental product for Phase 3 even after a carefully conducted Phase 2 program. One of the reasons is that patients exposed to the product in the Phase 2 program may be limited, and therefore, questions about the estimates of treatment effect are still remained. As a result, several possible doses of the product may be investigated further. An adaptive design combined with multiple doses of the experimental product in trials is thought to offer the opportunity to select the optimal dose of the product and demonstrate the efficacy and safety of the selected dose at trial completion. There are considerations as stated next.

A statistical issue of this type of adaptive design is whether the type I error is controlled. In fact, simulation results have shown that the type I error rate can be inflated if the withdrawal of an arm is based on data of the ongoing trial^[6] and no adjustment has been made. Such an inflation of the type I error rate can be significant in the case of the redistribution of the unused significance level to the remaining arms for comparisons after the withdrawal of a treatment arm. There is ample literature investigating the control of type I error and power^[7] for dose selection. Recently, unconditional and conditional approaches have been proposed for the one-winner treatment selection.^[8–10] Another issue for this adaptation feature is the safety profile of the experimental doses tested in the study. The selection of the optimal dose in this type of trial is mostly focused on efficacy. As a result, a most efficacious dose may be selected with, however, an unacceptable safety profile for the intended indication. This adaptation feature could be carefully explored using simulations under different scenarios. Dose response studies are considered to be conducted prior to embarking larger scale trials for product registration if there are many unknowns about product dose.

3. Change of the primary endpoint

The primary endpoint is the variable that is most relevant to the product indication and best reflects the

disease progression and the effect of treatment. To establish the efficacy of an experimental treatment for a specified indication, study results would need to show the benefit of the experimental treatment to the control (can be placebo) statistically and clinically with respect to the primary efficacy endpoint that is prespecified in the study. For many applications, primary endpoints are well established within the regulatory agencies and clinical societies. For example, in a heart failure clinical trial, the primary efficacy endpoint is usually a composite endpoint that consists of several components, such as deaths, myocardial infarction (MI), and stroke. Death or MI alone is not adequate to capture the progression of heart failure. It is possible in a heart failure clinical trial that an experimental treatment does not show effect statistically for the specified composite endpoint. It, however, may show a statistically significant effect for a different composite endpoint that consists of different components. However, changing the primary endpoint may alter the intended fundamental clinical/statistical questions, which are the originally planned hypotheses. This could contradict the confirmatory nature of trials for product registration purposes. Changing the primary endpoint based on results from ongoing trials that are intended to provide primary evidence for product registration may not be justifiable.

4. Changes between superiority to non-inferiority

Many active control trials in regulatory submissions in some disease areas do not incorporate a placebo arm because of ethical reasons. The effectiveness of the experimental product in active control trials in the absence of the placebo arm can be established via two strategies—the superiority of the experimental product to the active control product or the non-inferiority that the experimental product is not much worse than the active control product, and therefore, it would have been superior to placebo if the placebo had been in the trials. For the later strategy, the effectiveness of the control group must have been established previously compared to placebo in a well-controlled clinical trial setting, as the non-inferiority margin would rely on such information. The non-inferiority margin in a non-inferiority trial would need to be prespecified in regulatory submissions.

There is ample statistical literature regarding the consequences of determination of the non-inferiority margin based on the data derived from the current ongoing trials.^[11–13] The change of the non-inferiority margin based on the data observed during the course of the trial is not justifiable, and the study results may not be interpretable. In contrast, if a trial is planned to demonstrate non-inferiority and this is achieved based on interim results, there may be a motivation

to complete the study enrollment to demonstrate the superiority of the experimental treatment to the active control in efficacy and to generate more safety data. This possibility, however, should be planned in advance and should be prespecified in the protocol.

5. Selection of patient subgroups based on interim results

In clinical trials, there will be some differential responses to the experimental treatment for subgroups or strata of patients. Although it is desirable that results derived from a clinical trial are generalized to a wider patient population, sometimes interest may focus on patient subgroups that are most beneficial from the experimental treatment. On the other hand, when a substantial difference in responses between subgroups (or strata) is apparent, one is tempted to drop the patient stratum that is minimally responsive to the treatment as this may increase study power. Another reason for dropping a stratum is that the experimental treatment shows detrimental effect for the stratum of patients.^[14]

Adaptive selection of patient subgroups based on interim results has been proposed in regulatory submissions. Some even proposed to use results of point estimates to drop a patient stratum midway through the trial. One immediate concern is that it is not clear how to quantify the operating characteristics of the study. Simulated type I error rate may no longer correspond to the proper hypotheses to be tested as the assumptions made at the beginning of the simulation (wider patient population) may no longer be considered for rejection after study adaptation or at the end of the trial (narrower patient population). When relatively little information is available about which groups of patients would benefit from investigational treatment, study adaptation of selecting patient subgroups should be explored in the early phases of investigational treatment evaluation. It is of a great concern if the purpose of such study adaptation is to salvage trials that would otherwise be compromised due to low study powers or heterogeneous response across patient strata.

6. Simulations

Trial simulations play an important role in adaptive design studies, especially in trials that intend to provide substantial evidence for product registration. The major design properties of type I error rate and power of the trial often cannot be evaluated analytically in this type of trials. Trial simulations may greatly facilitate the evaluation of the type I error rate and power, the average sample size required, and the timing of interim analysis under various realistic scenarios. Simulations have variously been used to support novel study designs in regulatory submissions. Depending on the degree of complexity of a proposed adaptive design, extensive simulation

studies could be necessary. However, trial simulations require a variety of assumptions that may be difficult to justify and may well turn out to be false in practice. In any case where a final study outcome is out of the range of simulated scenarios at the planning stage, interpretation of the trial results might be complicated, and this could affect the FDA review of a premarketing application.

CASE STUDIES

Three case studies with features of study design adaptations are presented in this section.

Case Study 1

Indacaterol 75 mcg once daily was approved by the FDA in 2011 for bronchodilator treatment of airflow obstruction in patients with chronic obstructive pulmonary disease (COPD).^[15,16] The premarket application was initially submitted in 2008 for FDA review, where data generated from a two-stage Phase 3 adaptive design trial compared four doses of Indacaterol (75, 150, 300, or 600 mcg) to placebo, Formoterol, or Tiotropium in patients with COPD were included. The study was a double-blind, parallel-group, placebo-controlled, and randomized study with approximately 2000 patients planned. The primary efficacy endpoint was trough forced expiratory volume (FEV1) at 24 h post-dose after 12 weeks of treatment. A selection of optimal Indacaterol doses was made through a prespecified interim analysis. The final analysis used Bonferroni alpha adjustment for the four initial Indacaterol dose groups. Trial simulations were used to evaluate the statistical properties of the two-stage adaptive trial design. The trial schema is shown in Fig. 1.

Sponsor’s interim analysis resulted in the selection of two Indacaterol doses (150 and 300 mcg) to continue into stage 2. The final study results of each selected dose

were statistically significantly superior to placebo with a *p*-value smaller than 0.001. However, there were safety concerns regarding the selected 150 and 300 mcg doses. Cardiovascular (CV) and cerebrovascular adverse events as well as possible asthma-related deaths were observed in the selected Indacaterol groups. After further review of efficacy curves, the doses selected that were carried forward to stage 2 of the adaptive design trial were not justifiable. As a result, the sponsor conducted additional trials for dose–response and product registration that led to the approval of Indacaterol 75 mcg dose that was not evaluated in stage 2 of the two-stage adaptive design trial.

It is worth noting that the initial intent of the two-stage adaptive design trial was to select doses and to demonstrate superiority over active control arms, Formoterol or Tiotropium. This may subsequently result in the selection of higher doses of Indacaterol to carry forward to stage 2, and later yield unacceptable benefit–risk analysis. This case study also illustrates the importance of careful dose–response assessments in a product development. By combining dose selection and confirmation of the selected dose in one study, there is a risk that the selected dose may provide an unacceptable safety profile though it was shown to be highly statistically significant compared to placebo with respect to efficacy. This example also illustrates that the “white space” between separate Phase 2 and 3 trials in a conventional program can be useful and important as it permits thoughtful considerations of data collected prior to embarking a large scale of Phase 3 trials.

Case Study 2

This case study concerns the change of the primary endpoint during the course of CAPRICORN clinical trial. The study was designed as multinational, double-blind, parallel-group, and randomized. The objective was to study the effects of Carvedilol on mortality and morbidity in patients with left ventricular dysfunction, with or

Fig. 1 Schema of two-stage adaptive trial design

without clinical evidence of heart failure, or post MI compared with placebo.^[17] A total of 975 and 984 patients were randomized to receive Carvedilol and placebo, respectively. Study results were presented at the Cardiovascular Advisory Committee meeting in 2003.^[18]

At the study design stage, the primary endpoint was specified as all-cause mortality, and the secondary endpoint was a composite of mortality and CV hospitalization. One interim analysis of all-cause mortality at 125 deaths was planned in the original protocol. On the basis of evidence from outside of the trial (MERIT-HF), Data Safety Monitoring Board (DSMB) recommended an unplanned change in the primary endpoint to enhance study power. Recommendation was made prior to having carried out any efficacy analyses of the trial. As a result, the composite endpoint of mortality and CV hospitalization, which was originally pre-specified as a secondary endpoint, was added to be another primary endpoint, in addition to all-cause mortality. The study would be declared as a success if Carvedilol was superior to placebo in either one of the primary endpoints. For testing purpose and to preserve a study-wise type I error rate, the revised protocol assigned the primary endpoint, a composite of all-cause mortality and CV hospitalization, with a significance level of $\alpha = 0.045$, and the primary endpoint of all-cause mortality with a significance level of $\alpha = 0.005$, where $\alpha = 0.001$ for the interim analysis of mortality at 125 deaths and $\alpha = 0.004$ for the final analysis.

Following the study completion, the trial results did not meet the superiority comparison statistically in both primary endpoints ($p = 0.30$ and 0.031 for composite of all-cause mortality and CV hospitalization and all-cause mortality, respectively, which are greater than the nominal significance levels of 0.045 and 0.004). On the other hand, the study would have shown a statistical superiority of Carvedilol to placebo if the changing of endpoints at mid-course of the trial had not been implemented. One would argue that Carvedilol showed a statistically significant effect on the all-cause mortality endpoint as the p -value of 0.031 is less than a significance level of 0.05 . However, with the change of endpoints during the course of the trial, the comparison of $p = 0.031$ for the endpoint of all-cause mortality to 0.05 is no longer valid.

The change of primary endpoint in this case study was based on external information. There exists risk as the patient populations observed, and clinical practice, may be factors attributed to outcomes and resulted in different treatment effect sizes. The risk of changing endpoints using accumulated data in the same and ongoing trial is not eliminated as the degree of reliability of study results at the interim could be uncertain and whether subjects enrolled in the study earlier adequately represent the target population.

Case Study 3

Seamless Phase 2/3 adaptive design can sometimes be useful in some trial settings that eliminate unpromising doses

early, while carrying forward to Phase 3 only those doses that demonstrate potential public health benefit. Seamless Phase 2/3 adaptive design was implemented in a vaccine trial of Merck's recently approved 9-valent human papillomavirus vaccine (HPV-9). The study was designed to select the optimal dose among several doses in Phase 2 part and carried forward the selected dose to Phase 3 part for efficacy and safety. In this trial, Phase 2 part randomized subjects in an equal allocation to one of three HPV-9 vaccine doses or the control group Gardasil in a three-dose regimen. The best HPV-9 vaccine dose was selected based on immunogenicity and safety data analyzed at the interim analysis. Following selection of the optimal HPV-9 vaccine dose in Phase 2, a Phase 3 efficacy study enrolling an additional 13,380 subjects was conducted. These additional subjects combined with those subjects enrolled in Phase 2 who received the selected HPV-9 vaccine dose or the control vaccine Gardasil were evaluated for efficacy and safety to provide the primary evidence for product registration. In this case study, although the "white space" between Phase 2 and 3 trials in a conventional program as well as the End-of-Phase 2 meeting with the FDA was eliminated, there were several characteristics of the trial setting and product that supported the use of seamless design for this trial. First, the HPV-9 vaccine is a higher valent, which is the second-generation version of Gardasil, the 4-valent HPV vaccine approved in the United States in 2006. Consequently, there were limited unknowns about the HPV-9 vaccine. Second, the interim results were based on immunogenicity data for the four original serotypes (6/11/16/18) that are common to both the HPV-9 vaccine and Gardasil. There were clear criteria for dose selection. Efficacy assessment in the Phase 3 part was based on clinical endpoints related to the five new serotypes in HPV-9. Since there was low correlation expected between the immune responses for the four original serotypes and the efficacy outcomes for the five new serotypes, type I error inflation due to dose selection was expected to be minimal. The study protocol has specified a conservative statistical approach to estimate vaccine efficacy to mitigate any minimal type I error inflation that might occur. Third, several committees were involved in the dissemination of interim results. A sponsor internal committee that did not involve in the study performed the dose selection at the interim based only on immunogenicity data for the four original serotypes. The selected dose was confirmed by an external Data Monitoring Committee (DMC) based on both immunogenicity and safety. Firewalls on how interim results were disseminated were in place to protect the trial integrity. Following the completion of the trial, the sponsor performed simulations and results showed the control of type I error rate empirically for the seamless design. The simulations results also appear to show low correlation between the immune response and clinical efficacy endpoints. The final result of relative vaccine efficacy of HPV-9 compared to the 4-valent Gardasil was estimated to be 96%–97%, depending on case definition.

The above HPV-9 trial may be considered a successful implementation of a seamless Phase 2/3 adaptive design as different characteristics of trial setting and product supported the design. Whether an End-of-Phase 2 meeting with FDA is needed in the product development, it would depend on numerous factors, and the proposed trials intended to provide substantial evidence for product registration would need to be rigorously evaluated. The sponsor should discuss with regulators the possibility of a seamless Phase 2/3 adaptive design trial in advance when they intend to plan one for product registration.

CONCLUDING REMARKS

Adaptive designs have become recognized in clinical trials and other areas of public health research. For a clinical trial with adaptive study design, the central issues of concern are the clinical interpretation of overall trial results, operational logistics, trial conduct, and whether the integrity of study results is maintained. Methods that simply gain control over the type I error rate are not adequate. Issues, such as the operational biases and characteristics due to interim looks of data, and pooling data before and after design adaptations, make the regulatory evaluation of outcomes generated from adaptive design trials more complex and challenge. Sponsors may propose adaptive design clinical trials when appropriate for their product development. One, however, should recognize that the best study design proposals may not be adaptive designs. Sometimes, a simpler design is most efficient. As indicated in a survey summary paper,^[19,20] the number of adaptive design submissions in CBER and CDRH did not continue to increase after the release of the FDA Draft Guidance for drugs and biologics. Our experience indicates that whether an adaptive feature can actually benefit a study may depend on a number of factors. For example, early-stage studies (e.g., Phase 1/2 or feasibility/pilot) with adaptive design elements are generally encouraged to explore. Trials that are intended to provide primary evidence for product registration would require more rigorous reviews and deliberations. We provide the following points for considerations when an adaptive design clinical trial is planned for product registration purposes:

1. What are the advantages of using an adaptive design instead of a conventional design (**why**)?
2. What adaptation features does the proposed design plan (**what**)?
3. How is the adaptive design conducted?
 - Are details related to timing and execution clearly specified in the protocol?
 - Is the study-wise type I error rate controlled? If simulations are used to demonstrate the control of type I error rate, are the included simulation studies adequate?

- Are strategies and logistics being planned to mitigate the operational bias? Are study decision rules, success criteria, and stopping rules clearly specified?

Finally, it should be emphasized that the added flexibility of adaptation is not without potential pitfalls. Sponsors are expected to address the issues laid out in the article when they propose an adaptive design clinical trial in regulatory submissions. Study adaptation should never be used as a way to salvage study results and should never be used to avoid careful planning through research and development of medical products during the development process.

Abstract

The aim of this entry is not only to provide a comprehensive summarization of the issues that are commonly encountered when applying/implementing the adaptive design methods in clinical research but also to include recent development such as the role of the independent data safety monitoring board and sample size estimation/allocation, justification, and adjustment when implementing a much more complicated adaptive design in clinical trials.

Keywords: Adaptive Design; Flexible Design; Group Sequential Design; Adaptive design in clinical trials; Flexible SSRE design.

INTRODUCTION

In the past several decades, it has been recognized that increasing spending of biomedical research does not reflect an increase of the success rate of pharmaceutical/clinical research and development. The low success rate of pharmaceutical/clinical development could be due to following factors: (i) there is a diminished margin for improvement that escalates the level of difficulty in proving drug benefits, (ii) genomics and other new sciences have not yet reached their full potential, (iii) mergers and other business arrangements have decreased candidates, (iv) easy targets are the focus as chronic diseases are harder to study, (v) failure rates have not improved, and (vi) rapidly escalating costs and complexity decreases the willingness/ability to bring many candidates forward into the clinic.^[1] In early 2000, the U.S. Food and Drug Administration (FDA) kicked off the Critical Path Initiative to assist the sponsors in (i) identifying possible causes, (ii) providing resolutions, and (iii) increasing the efficiency and the probability of success in pharmaceutical research and development. In its 2004 Critical Path Report, the FDA presented its diagnosis of the scientific challenges underlying the medical product pipeline problems. Two years later, the FDA released a Critical Path Opportunities List that calls for advancing innovative trial designs by using prior experience or accumulated information in trial design. Many researchers interpret it as the encouragement of using innovative adaptive design methods in clinical trials, while some researchers believe it is the recommendation for the use of Bayesian approach for assessment of treatment effect in pharmaceutical/clinical development. The purpose of adaptive design methods in clinical trials is

to provide the flexibility to the investigator for identifying best (optimal) clinical benefit of the test treatment under study in a timely and efficient fashion without undermining the validity and integrity of the intended study.

The concept of adaptive design can be traced back to 1970s when adaptive randomization (play-the-winner) and a class of designs for sequential clinical trials were introduced.^[2] As a result, most adaptive design methods in clinical research and development are referred to as adaptive randomization,^[3–8] group sequential designs with the flexibility for stopping a trial early due to safety, futility and/or efficacy,^[9–13] and flexible sample size re-estimation at interim for achieving the desired statistical power by controlling the overall type I error rate at a pre-specified level of significance.^[14–16] The use of adaptive design methods for modifying the trial procedures and/or statistical methods of ongoing clinical trials based on accrued data has been practiced for years in pharmaceutical/clinical research and development. Adaptive design methods in clinical research are very attractive to pharmaceutical/clinical scientists for the following reasons. First, it reflects medical practice in real world. Second, it is ethical with respect to both efficacy and safety (toxicity) of the test treatment under investigation. Third, it is not only flexible but also efficient in the early phase of clinical development. However, one concern is whether the p-value or confidence interval regarding the treatment effect obtained after the modification is correct or reliable. In addition, another concern is that the use of adaptive design methods in a clinical trial may lead to a totally different trial that is unable to address scientific/medical questions that the trial is intended to answer.

In recent years, the potential use of adaptive design methods in clinical trials has attracted much attention.

For example, the Pharmaceutical Research and Manufacturers of America (PhRMA) and Biotechnology Industry Organization (BIO) have established adaptive design working groups and proposed/published white papers regarding strategies, methodologies, and implementations for regulatory consideration.^[17,18] However, there is no universal agreement in terms of definition, methodologies, applications, and implementations. In addition, many journals have also published special issues on adaptive design for evaluation the potential use of adaptive trial design methods in clinical research and development. These scientific journals include, but are not limited to, *Biometrics* (Vol. 62, No. 3), *Statistics in Medicine* (Vol. 25, No. 19), *Journal of Biopharmaceutical Statistics* (Vol. 15, No. 4 and Vol. 17, No. 6), *Biometrical Journal* (Vol. 48, No. 4), and *Pharmaceutical Statistics* (Vol. 5, No. 2). In addition, many professional conferences/meetings have devoted special sessions for discussion of the feasibility, applicability, efficiency, validity, and integrity of the potential use of the innovative adaptive design methods in clinical trials in the past several years. For example, the FDA/Industry Statistics Workshop has offered adaptive sessions and workshops from industrial, academic, and regulatory perspectives consecutively between 2006 and 2008. More details regarding the use of adaptive design methods in clinical trials can be found in the books by Chow and Chang^[19] and Chang^[18].

The purpose of this entry is not only to provide a comprehensive summarization of the issues that are commonly encountered when applying/implementing the adaptive design methods in clinical research but also to include recently development such as the role of the independent data safety monitoring board and sample size estimation/allocation, justification, and adjustment when implementing a much more complicated adaptive design in clinical trials. In the next section, commonly employed adaptations and the resultant adaptive designs are briefly described. Also included in this section are regulatory and statistical perspectives regarding the use of adaptive design methods in clinical trials. The impact of protocol amendments, challenges of by design adaptations, and obstacles of retrospective adaptations when applying adaptive design methods in clinical trials are described in the section “Impact, Challenges, and Obstacles”. Some trial examples and strategies for clinical development are discussed in the sections “Some Examples” and “Strategies for Clinical Development,” respectively. A brief concluding remark is given in the last section.

WHAT IS ADAPTIVE DESIGN?

In clinical trials, it is not uncommon to modify trial procedures and/or statistical methods during the conduct of clinical trials based on the review of accrued data at

interim. The purpose is not only to efficiently identify clinical benefits of the test treatment under investigation but also to increase the probability of success of the intended clinical trial. Trial procedures are referred to as the eligibility criteria, study dose, treatment duration, study endpoints, laboratory testing procedures, diagnostic procedures, criteria for evaluability, and assessment of clinical responses. Statistical methods include randomization scheme, study design selection, study objectives/hypotheses, sample size calculation, data monitoring and interim analysis, statistical analysis plan, and/or methods for data analysis. In this chapter, we will refer to the adaptations (changes or modifications) made to the trial and/or statistical procedures as the adaptive design methods. Thus, an adaptive design is defined as a design that allows adaptations to trial and/or statistical procedures of the trial after its initiation without undermining the validity and integrity of the trial.^[20] In one of their publications, with the emphasis of the feature of by design adaptations only (rather than ad hoc adaptations), the PhRMA Working Group on Adaptive Design refers to an adaptive design as a clinical trial design that uses accumulating data to decide on how to modify aspects of the study as it continues, without undermining the validity and integrity of the trial.^[17] In many cases, an adaptive design is also known as a flexible design.^[21,22]

Adaptations

An adaptation is referred to as a modification or a change made to trial procedures and/or statistical methods during the conduct of a clinical trial. By definition, adaptations that are commonly employed in clinical trials can be classified into the categories of prospective adaptation, concurrent (or ad hoc) adaptation, and retrospective adaptation. Prospective adaptations include, but are not limited to, adaptive randomization; stopping a trial early due to safety, futility, or efficacy at interim analysis; dropping the losers (or inferior treatment groups); sample size re-estimation; and so on. Thus, prospective adaptations are usually referred to as by design adaptations as described in the PhRMA white paper.^[17] Concurrent adaptations are usually referred to as any ad hoc modifications or changes made as the trial continues. Concurrent adaptations include, but are not limited to, modifications in inclusion/exclusion criteria, evaluability criteria, dose/regimen and treatment duration, changes in hypotheses and/or study endpoints, and so on. Retrospective adaptations are usually referred to as modifications and/or changes made to statistical analysis plan prior to database lock or unblinding of treatment codes. In practice, prospective, ad hoc, and retrospective adaptations are implemented by study protocol, protocol amendments, and statistical analysis plan with regulatory reviewer's consensus, respectively.

Types of Adaptive Designs

Based on the adaptations employed, commonly considered adaptive designs in clinical trials include, but are not limited to (i) adaptive randomization design, (ii) group sequential design, (iii) N-adjustable (or flexible sample size re-estimation) design, (iv) drop-the-losers design, (v) adaptive dose finding design, (vi) biomarker-adaptive design, (vii) adaptive treatment-switching design, (viii) adaptive-hypothesis design, (ix) adaptive seamless (e.g., phase I/II or phase II/III) trial design, and (x) multiple adaptive design. These adaptive designs are briefly described below.

Adaptive Randomization Design

An adaptive randomization design is a design that allows modification of randomization schedules based on varied and/or unequal probabilities of treatment assignment in order to increase the probability of success. As a result, an adaptive randomization design is sometimes referred to as a play-the-winner design since it will increase the probability of success. Commonly applied adaptive randomization procedures include treatment-adaptive randomization,^[3,4] covariate-adaptive randomization, and response-adaptive randomization.^[6,8]

Although an adaptive randomization design could increase the probability of success, it may not be feasible for a large trial or a trial with relatively longer treatment duration because the randomization of a given subject depends on the response of the previous subject. A large trial or a trial with a relatively longer treatment duration utilizing adaptive randomization design will take a much longer time to complete. Besides, the randomization schedule may not be available prior to the conduct of the study. Moreover, statistical inference on treatment effect is often difficult to obtain due to the complexity of the randomization scheme. In practice, a statistical test is often difficult, if not impossible, to obtain due to complicated probability structure as the result of adaptive randomization, which has also limited the potential use of adaptive randomization design in practice.

Group Sequential Design

A group sequential design is a design that allows for prematurely stopping a trial due to safety, futility/efficacy, or both with options of additional adaptations based on results of interim analysis. Many researchers refer to a group sequential design as a typical adaptive design because some adaptations may be applied after the review of interim results of the study, such as stopping the trial early due to safety, efficacy, and/or futility. In practice, various stopping boundaries based on different boundary functions for controlling an overall type I error rate are available in the literature.^[6,9,10,19,23,24] In recent years,

the concept of two-stage adaptive design has led to the development of the adaptive group sequential design.^[11–14]

It should be noted that when additional adaptations such as adaptive randomization, dropping the losers, and/or adding additional treatment arms (in addition to the commonly considered adaptations such as stop the trial early due to safety, efficacy and/or futility and sample size re-estimation, and so on) are applied to a typical group sequential design after the review of the interim results, the resultant group sequential design is usually referred to as an adaptive group sequential design. In this case, the standard methods for the typical group sequential design may not be appropriate. In addition, it may not be able to control the overall type I error rate at the desired level of 5% if (i) there are additional adaptations (e.g., changes in hypotheses and/or study endpoints) and/or (ii) there is a shift in target patient population due to additional adaptations or protocol amendments.

Flexible Sample Size Re-Estimation (SSRE) Design

A flexible sample size re-estimation (or N-adjustable) design is referred to as an adaptive design that allows for sample size adjustment or re-estimation based on the observed data at interim. In clinical research, it can be verified that the selected sample size is a function of type I error rate, type II error rate (or power), treatment effect (or clinically meaningful difference), and variability associated with the response. A typical approach (power analysis) is to select a sample size that will achieve a desired power by fixing other parameters such as type I error rate, the clinically meaningful difference, and the variability associated with the response. In practice, it is impossible to select a sample size that controls all parameters. For a flexible SSRE design, sample size adjustment or re-estimation could be done in either a blinding or unblinding fashion based on the criteria of maintaining anticipated treatment effect-size, controlling variability within a tolerable limit, achieving a desired conditional power, and/or reaching certain degree of reproducibility probability.^[11,14–16,25–28] Thus, sample size in a flexible SSRE trial design is a random variable. Sample size re-estimation suffers from the same disadvantage as the original power analysis for sample size calculation prior to the conduct of the study because it is performed by treating estimates of the study parameters, which are obtained based on data observed at interim, as true values. Note that the criteria of maintain treatment effect size, controlling variability, and achieving conditional power are considered one-parameter problem, while the criterion of reaching reproducibility is a two-parameter problem.

According to an informal communication with the medical/statistical reviewers at the FDA, it is not a good clinical/statistical practice to start with a small number and then perform sample size re-estimation (adjustment) at interim by ignoring the clinically meaningful difference

that one wishes to detect for the intended clinical trial. It should be noted that the observed difference at interim based on a small number of subjects may not be of statistical significance (i.e., it may be observed by chance alone). In addition, there is variation associated with the observed difference which is an estimate of the true difference. Thus, standard methods for sample size re-estimation based on the observed difference with a limited number of subjects may be biased and misleading. To overcome these problems, in practice, a sensitivity analysis (with respect to variation associated with the observed results at interim) for sample size re-estimation design is recommended.

Drop-The-Losers Design

A drop-the-losers design is a design that allows dropping the inferior treatment groups as well as adding additional (promising) arms. A drop-the-losers design is useful in early phase of clinical development especially when there are uncertainties regarding the dose levels.^[29–32] The selection criteria (including the selection of initial dose, the increment of the dose, and the dose range) and decision rules play important roles for drop-the-losers designs. Dose groups that are dropped may contain valuable information regarding dose response of the treatment under study. Typically, drop-the-losers design is a two-stage design. At the end of the first stage, the inferior arms will be dropped based on some pre-specified criteria. The winners will then proceed to the next stage. In practice, the study is often powered for achieving a desired power at the end of the second stage (or at the end of the study). In other words, there may not be any statistical power for the analysis at the end of the first stage for dropping the losers (or picking up the winners).

In practice, it is not uncommon to drop the losers or pick up the winners based on so-called precision analysis.^[16] The precision approach is an approach based on the confidence level for achieving statistical significance. In other words, the decision will be made (i.e., to drop the losers) if the confidence level for observing a statistical significance (i.e., the observed difference is not by chance alone or it is reproducible with the pre-specified confidence level) is exceed a pre-specified confidence level. In addition, other criteria for dropping the losers such as predictive probability of success and probability of being the best dose (or treatment arm) are also commonly considered.^[69] Liu et al (2017) compared relative performances of these criteria in terms of the probability of correctly identifying the most promising dose (treatment arm) under a two-stage adaptive trial design.^[70]

Note that in a drop-the-losers design, a general principle is to drop the inferior treatment groups or add promising treatment arms but at the same time it is suggested that the control group be retained for a fair and reliable comparison at the end of the study. It should be noted that dose groups that are dropped may contain valuable information

regarding dose response of the treatment under study. In practice, it is also suggested that subjects who are assigned in the inferior dose groups should be switched to the better dose group for ethical consideration. Treatment switching in a drop-the-losers design could complicate statistical evaluation in the dose selection process. Note that some clinical scientists prefer the term pick-the-winners rather than drop-the-losers.

Adaptive Dose Finding Design

The purpose of an adaptive dose finding (e.g., escalation) design is multifold and includes (i) the identification whether there is a dose response, (ii) the determination of the minimum effective dose (MED) and/or the maximum tolerable dose (MTD), (iii) the characterization of dose response curve, and (iv) the study of dose ranging. The information obtained from an adaptive dose finding experiment is often used to determine the dose level for the next phase of clinical development.^[33–35] For adaptive dose finding design, the method of continual re-assessment method (CRM) in conjunction with Bayesian approach is usually considered.^[36–38] Mugno et al.^[39] introduced a non-parametric adaptive urn design approach for estimating a dose-response curve. More details regarding PhRMA's proposed statistical methods, the reader should consult with a special issue recently published at the Journal of Biopharmaceutical Statistics, Vol. 17, No. 6. Note that a typical approach for adaptive dose finding design focuses on dose response (severe toxicity and/or tolerability) curve. In practice, it is suggested that both safety including mild-to-moderate toxicity and efficacy be considered.

Note that according to the ICH E4 guideline on Dose-response Information to Support Drug Registration, there are several types of dose-finding (response) designs, which are (i) randomized parallel dose-response designs, (ii) crossover dose-response design, (iii) forced titration design (dose escalation design), and (iv) optimal titration design (placebo-controlled titration to endpoint). Some commonly asked questions for an adaptive dose finding design include, but are not limited to, (i) how to select the initial dose, (ii) how to select the dose range under study, (iii) how to achieve statistical significance with a desired power with a limit number of subjects, and (iv) what the selection criteria and decision rules should be if one would like to make a decision based on safety, tolerability, efficacy and/or pharmacokinetic information, and (v) what the probability is of achieving the optimal dose. In practice, a clinical trial simulation and/or sensitivity analysis is often recommended to evaluate/address the above questions.

Biomarker-Adaptive Design

A biomarker-adaptive design is a design that allows for adaptations based on the response of biomarkers such as genomic markers. An adaptive biomarker design involves

biomarker qualification and standard, optimal screening design, and model selection and validation. It should be noted that there is a gap between identifying biomarkers that associated with clinical outcomes and establishing a predictive model between relevant biomarkers and clinical outcomes in clinical development. For example, correlation between a biomarker and a true clinical endpoint makes a prognostic marker. However, correlation between a biomarker and a true clinical endpoint does not make a predictive biomarker. A prognostic biomarker informs the clinical outcomes, independent of treatment. They provide information about the natural course of the disease in individuals who have or have not received the treatment under study. Prognostic markers can be used to separate good- and poor-prognosis patients at the time of diagnosis. A predictive biomarker informs the treatment effect on the clinical endpoint.^[18]

A biomarker-adaptive design can be used to (i) select right patient population (e.g., enrichment process for selection of a better target patient population), (ii) identify nature course of disease, and (iii) detect disease earlier. In clinical research and development, biomarker-adaptive design, which has led to the research of targeted clinical trials, is not only the key to the success of precision medicine, but also help in developing personalized medicine.^[18,40,41]

Adaptive Treatment-Switching Design

An adaptive treatment-switching design is a design that allows the investigator to switch a patient's treatment from an initial assignment to an alternative treatment if there is evidence of lack of efficacy or safety of the initial treatment.^[42,43] In cancer clinical trials, estimation of survival is a challenge when treatment-switching has occurred in some patients. A high percentage of subjects who switched due to disease progression could lead to change in hypotheses to be tested. In this case, sample size adjustment for achieving a desired power is necessary.

Adaptive-Hypotheses Design

An adaptive-hypotheses design refers to a design that allows modification or change in hypotheses based on interim analysis results.^[44] Adaptive-hypotheses designs are often considered before database lock and/or prior to data unblinding, which are implemented by the development of statistical analysis plan (SAP). Typical examples include the switch from a superiority hypothesis to a non-inferiority hypothesis and the switch between the primary study endpoint and the secondary endpoints. The purpose for switching from a superiority hypothesis to a non-inferiority hypothesis is to increase the probability of the success of the clinical trial. A typical approach is to first establish non-inferiority and then test for superiority. In this way, we do not have to pay for statistical penalty due to the principle of closed testing procedure. The idea of

switching the primary study endpoints and the secondary endpoints is also to increase the probability of success of clinical development. In practice, it is not uncommon to observe positive results in secondary endpoint while fail to demonstrate clinical benefit for the primary endpoints. In this case, there is a strong desire to switch the primary endpoints and the secondary endpoints whenever it is scientifically, clinically, and regulatory justifiable.

It should be noted that, for the switch from a superiority hypothesis to a non-inferiority hypothesis, the selection of non-inferiority margin is critical and has an impact on sample size adjustment for achieving the desired power. According to the ICH guideline, the selected non-inferiority margin should be both clinical and statistical justifiable.^[45,46] Regarding the switch between the primary endpoint and the secondary endpoints, there has been a tremendous debate about controlling the overall type I error rate at the 5% level of significance. Thus, as an alternative, it has been recommended by many researchers considering switching from the primary endpoint to either a co-primary endpoint or a composite endpoint. However, the optimal allocation of the alpha spending function has raised another statistical/clinical/regulatory concern.

Seamless Adaptive Trial Design

A seamless adaptive trial design refers to a program that addresses within single trial objectives that are normally achieved through separate trials of clinical development. A seamless adaptive design is a trial design that would use data from patients enrolled before and after the adaptation in the final analysis.^[47–49] Commonly considered adaptive seamless trials in clinical development include an adaptive seamless phase I/II design in early clinical development and an adaptive seamless phase II/III trial design in late phase clinical development.

An adaptive seamless phase II/III design is a two-stage design consisting of a learning or exploratory stage (phase IIb) and a confirmatory stage (phase III). A typical approach is to power the study for the phase III confirmatory phase and obtain valuable information with certain assurance using confidence interval approach at the phase II learning stage. Its validity and efficiency, however, has been challenged.^[50–52] Statistical methods for a combined analysis under the situation that the study objectives (and/or endpoints) are similar but different at different stages are studied in the literature.^[71] One of the key assumptions is that there is a well-established relationship between study endpoints at different stages. In other words, study endpoint (e.g., biomarker, surrogate endpoint, or same clinical endpoint with shorter duration) at earlier stage is predictive of study endpoint (e.g., clinical endpoint) at later stage. More research regarding sample size estimation/allocation and statistical analysis for seamless adaptive designs with different study objectives and/or

study endpoints for various data types (e.g., continuous, binary, and time-to-event) is needed.

Most recently, on August 9, 2016, the FDA allows a sponsor to conduct a phase II/III/IV seamless adaptive clinical trial for NASH (Non-Alcoholic SteatoHepatitis) studies. This is very encouraging to the sponsors. However, statistical methods for multiple-stage seamless adaptive trial design of this kind is not fully developed. More research on this topic is necessary.

Multiple Adaptive Design

Finally, a multiple adaptive design is any combinations of the above adaptive designs. Commonly considered multiple adaptive designs include (i) the combination of adaptive group sequential design, drop-the-losers design, and adaptive seamless trial design and (ii) adaptive dose-escalation design with adaptive randomization.^[19] In practice, because statistical inference for a multiple-adaptation design is often difficult, it is suggested that a clinical trial simulation be conducted to evaluate the performance of the resultant multiple adaptive design at the planning stage.

When applying a multiple adaptive design, some frequently asked questions include (i) how to avoid/control potential operational biases which may be introduced due to various adaptations that apply to the trial, (ii) how to control the overall type I error rate at the 5%, (iii) how to determine the required sample size for achieving the study objectives with the desired power, and (iv) how to maintain the quality, validity, and integrity of the trial. The tradeoff between the flexibility/efficiency and scientific validity/integrity needs to be carefully evaluated before a multiple adaptive design is implemented in clinical trials.

Regulatory/Statistical Perspectives

From a regulatory point of view, the use of adaptive design methods based on accrued data in clinical trials may introduce operational bias such as selection bias, method of evaluation, early withdrawal, and modification of treatment. Consequently, it may not be able to preserve the overall type I error rate at the pre-specified level of significance. In addition, p-values may not be correct and the corresponding confidence intervals for the treatment effect may not be reliable. Moreover, it may result in a totally different trial that is unable to address the medical questions that original study intended to answer. Li^[53] also indicated that commonly seen adaptations that have an impact on the type I error rate include, but are not limited to, (i) sample size adjustments at interim, (ii) sample size allocations to treatments, (iii) deletions of, additions to, or changes to treatment arms, (iv) shifts in target patient population such as changes in inclusion/exclusion criteria, (v) changes in statistical test strategy, (vi) changes in study endpoints, and (vii) changes in study objectives such as the

switch from a superiority trial to a non-inferiority trial. As a result, it is difficult to interpret the clinically meaningful effect size for the treatments under study.^[54]

From a statistical point of view, major (or significant) adaptations to trial and/or statistical procedures could (i) introduce bias/variation to data collection, (ii) result in a shift in location and scale of the target patient population, and (iii) lead to inconsistency between hypotheses to be tested and the corresponding statistical tests. These concerns will not only have an impact on the accuracy and reliability of statistical inference drawn on the treatment effect but also present challenges to biostatisticians for development of appropriate statistical methodology for an unbiased and fair assessment of the treatment effect.

Note that although the flexibility of modifying study parameters is very attractive to clinical scientists, several regulatory questions/concerns arise. First, what level of modifications to the trial procedures and/or statistical procedures would be acceptable to the regulatory authorities? Second, what are the regulatory requirements and standards for review and approval process of clinical data obtained from adaptive clinical trials with different levels of modifications to trial procedures and/or statistical procedures of ongoing clinical trials? Third, has the clinical trial become a totally different clinical trial after the modifications to the trial procedures and/or statistical procedures for addressing the study objectives of the originally planned clinical trial? These concerns should be addressed by the regulatory authorities before the adaptive design methods can be widely accepted in clinical research and development.

IMPACT, CHALLENGES, AND OBSTACLES

Impact of Protocol Amendments

In practice, for a given clinical trial, it is not uncommon to have between three and five protocol amendments after the initiation of the clinical trial. One of the major impacts of many protocol amendments is that the target patient population may have been shifted during the process, which may have resulted in a totally different target patient population at the end of the trial. A typical example is the case when significant modifications are applied to inclusion/exclusion criteria of the study protocol. As a result, the resultant actual patient population following certain modifications to the trial procedures is a moving target patient population rather than a fixed target patient population. As indicated in Chow and Chang,^[19] the impact of protocol amendments on statistical inference due to shift in target patient population (moving target patient population) can be studied through a model that link the moving population means with some covariates.^[55] Chow and Shao^[55] derived statistical inference for the original target patient population for simple cases.

Challenges in By Design Adaptations

In clinical trials, commonly employed prospective (by design) adaptations include stopping the trial early due to safety, futility, and/or efficacy, sample size re-estimation (adaptive group sequential design), dropping the losers (adaptive dose finding design), and combining two separate trials into a single trial (adaptive seamless design). These designs are typical multiple-stage designs with different adaptations. In this section, major challenges in analysis and design are described. Recommendations and future development for resolution are provided whenever possible.

The major difference between a classic multiple-stage design and an adaptive multiple-stage design is that an adaptive design allows adaptations after the review of interim analysis results. These by-design adaptations include sample size adjustment (re-assessment or re-estimation), stopping the trials due to safety, efficacy/futility, or dropping the losers (picking the winners). Note that commonly considered adaptive group sequential design, adaptive dose finding design, and adaptive seamless trial design are special cases of multiple-stage designs with different adaptations. In this section, we will discuss major challenges in design (e.g., sample size calculation) and analysis (controlling type I error rate under moving target patient population) of an adaptive multiple-stage design with $K - 1$ interim analyses.

A multiple-stage adaptive group sequential design is very attractive to sponsors in clinical development. However, major (or significant) adaptations such as modification of doses and/or change in study endpoints may introduce bias/variation to data collection as the trial continues. To account for these (expected and/or unexpected) biases/variation, statistical tests are necessary adjusted to maintain the overall type I error, and the related sample size calculation formulas have to be modified for achieving the desired power. In addition, the impact on statistical inference is not negligible if the target patient population has been shifted due to major or significant adaptations and/or protocol amendments. This has presented challenges to biostatisticians in clinical research when applying a multiple-stage adaptive design. In practice, thus, it is worthy pursuing the following specific directions: (i) derive valid statistical test procedures for adaptive group sequential designs assuming model, which relates the data from different interim analyses, (ii) derive valid statistical test procedures for adaptive group sequential designs assuming the random-deviation model, (iii) derive valid Bayesian methods for adaptive group sequential designs, and (iv) derive sample size calculation formulas for various situations. Tsiatis and Mehta^[50] showed that there exists an optimal (i.e., uniformly more powerful) design for any class of sequential design with a specified error spending function. It should be noted that adaptive designs do not require in general a fixed error spending function. One of

major challenges for an adaptive group sequential design is that the overall type I error rate may be inflated when there is a shift in target patient population.^[56]

For adaptive dose-finding design, Chang and Chow's method can be improved by the following specific directions: (i) study the relative merits and disadvantage of their method under various adaptive methods, (ii) examine the performance of an alternative method by forming the utility first with different weights to the response levels and then modeling the utility, and (iii) derive sample size calculation formulas for various situations. An adaptive seamless phase II/III design is a two-stage design that consists of two phases namely a learning (or exploratory) phase and a confirmatory phase. One of the major challenges for designs of this kind is that different study endpoints are often considered at different stages for achieving different study objectives. In this case, the standard statistical methodology for assessment of treatment effect and for sample size calculation cannot be applied.

For a two-stage adaptive design, the aforementioned method by Chang^[57] can be applied. Chang's method, however like other stagewise combination methods, is valid under the assumption of constancy of the target patient populations, study objectives, and study endpoints at different stages.

Obstacles of Retrospective Adaptations

In practice, retrospective adaptations such as adaptive-hypotheses may encounter prior to database lock (or unblinding) and be implemented through the development of statistical analysis plan. To illustrate the impact of retrospective adaptations, we first consider the situation where switching hypotheses between a superiority hypothesis and a non-inferiority hypothesis. For a promising test drug, the sponsor would prefer an aggressive approach for planning a superiority study. The study is usually powered to compare the promising test drug with an active control agent.

However, the collected data may not support superiority. Instead of declaring the failure of the superiority trial, the sponsor may switch from testing superiority to testing the following non-inferiority hypotheses. The margin is carefully chosen to ensure that the treatment of the test drug is larger than the placebo effect and, thus, declaring non-inferiority to the active control agent means that the test drug is superior to the placebo effect. The switch from a superiority hypothesis to a non-inferiority hypothesis will certainly increase the probability of success of the trial because the study objective has been modified to establishing non-inferiority rather than showing superiority. This type of switching hypotheses is recommended provided that the impact of the switch on statistical issues and inference (e.g., appropriate statistical methods) on the assessment of treatment effect is well justified.

SOME EXAMPLES

In this section, we will present some examples for adaptive trial designs, which have been implemented in practice.^[58] These trial examples include (i) an adaptive dose escalation design for early phase cancer trials, (ii) a multiple-stage adaptive design for Non-Hodgkin's Lymphoma (NHL) trial, (iii) a phase IV drop-the-losers adaptive design for multiple myeloma trial, and (iv) a two-stage seamless phase I/II adaptive trial design for hepatitis C virus (HCV) trial, which are described below.

Example 1: Adaptive dose escalation design for early phase cancer trials

In a phase I cancer trial, suppose that the primary objective is to identify the maximum tolerated dose (MTD) for a new test drug. Based on the animal studies, it is estimated that the toxicity (dose limiting toxicity rate) is 1% for the starting dose 25 mg/m² (one-tenth of the lethal dose). The dose limiting toxicity (DLT) rate at MTD is defined as 0.25 and the MTD is estimated to be 150 mg/m². A typical approach is to consider so-called 3 + 3 traditional escalation rule (TER). On the other hand, an adaptive type approach is to apply the continual re-assessment method (CRM) in conjunction with a Bayesian approach. We can compare the 3 + 3 TER approach and the Bayesian CRM adaptive method through simulations. A logistic toxicity model is chosen for the simulations. The dose interval sequence is chosen to be the customized dose increment sequence (Increment factors = 2, 1.67, 1.33, 1.33, 1.33, 1.33, 1.33, 1.33). The evaluations of the escalation designs are based on the criteria of safety, accuracy, and efficiency. Simulation results for all three methods for three different MTD scenarios are summarized in Table 1.

In this example, as it can be seen that if the true MTD is 150 mg/m², the TER approach underestimates MTD (125 mg/m²), whereas the Bayesian CRM adaptive method also slightly underestimates the MTD (141 mg/m²). The average number of patients required is 19.4 and 15.5 for the TER approach and the Bayesian CRM adaptive method, respectively. From a safety perspective, the average number of DLTs is 2.9 and 2.5 per trial for the TER approach and the Bayesian CRM, respectively. As a result, the Bayesian CRM adaptive method is preferable. More details regarding Bayesian CRM adaptive method and adaptive dose finding can be found in Chang and Chow^[38].

Example 2: Multiple-stage adaptive design for NHL trial

A phase III two parallel group Non-Hodgkin's Lymphoma trial was designed with three analyses. The primary endpoint is progression-free survival (PFS), the secondary endpoints are (i) overall response rate (ORR) including complete and partial response and (ii) complete response rate (CRR). The estimated median PFS is 7.8 months and 10 months for the control and test groups, respectively. Assume a uniform enrollment with an accrual period of 9 months and a total study duration of 23 months. The estimated ORR is 16% for the control group and 45% for the test group. The classic design with a fixed sample size of 375 subjects per group will allow for detecting a three-month difference in median PFS with 82% power at a one-sided significance level of $\alpha = 0.025$. The first interim analysis will be conducted on the first 125 patients/group (or total $N_1 = 250$) based on ORR. The objective of the first IA is to modify the randomization. Specifically, if the difference in ORR (test-control), $\Delta_{\text{ORR}} > 0$, the enrollment will continue. If $\Delta_{\text{ORR}} \leq 0$, then the enrollment will stop. If the enrollment is terminated prematurely, there will be one final analysis for efficacy based on PFS and possible efficacy claimed on the secondary endpoints. If the enrollment continues, there will be a second interim analysis based on PFS. The second interim analysis will could lead to either claim efficacy or futility, or continue to the next stage with possible sample size re-estimation. For the final analysis of PFS, when the primary endpoint (PFS) is significant, the analyses for the secondary endpoints will be performed for the potential claim on the secondary endpoints. During the interim analyses, the patient enrollment will not stop.

Example 3: Drop-the-losers adaptive design for multiple myeloma trial

For phase IV study, the adaptive design can also work well. For example, a year after an oncology drug came on the market, physicians are using the drug with different combinations for treating patients with multiple myeloma (MM). However, there is a strong desire to know which combination is the best for the patient populations. Many physicians have their own experiences, but no one has convincing data. Therefore, the sponsor is planned a trial to investigate the optimal combination for the drug. In this scenario, we can use much smaller sample size than we would in phase III trials because the issue is focused on the type I control as the drug is approved. The issue is as follows: given a minimum

Table 1 Summary of Simulation Results for the Designs

Method	True MTD	Mean predicted MTD	Mean number of patients	Mean number of DLTs
3 + 3 TER	100	86.7	14.9	2.8
CRM	100	99.2	13.4	2.8
3 + 3 TER	150	125	19.4	2.9
CRM	150	141	15.5	2.5
3 + 3 TER	200	169	22.4	2.8
CRM	200	186	16.8	2.2

Table 2 Simulation Results of Phase IV Drop-the-Losers Design

Interim sample size per group	Final sample size per group	Probability of identifying the optimal arm (%)
25	50	80.3
50	100	91.3

Note: Response rate for the five arms: 0.4, 0.45, 0.45, 0.5, and 0.6.
Source: From Ref. [58].

clinically meaningful difference (e.g., two weeks in survival), what is the probability of the trial will be able to identify the optimal combination? Again this can be done through simulations, the strategy is to start with about five combinations, drop inferior arms, and calculate the probability of selecting the best arm under different combinations of sample size at the interim and final stages. In this adaptive design, we will drop two arms based on the observed response rate, that is, the two arms with lowest observed response rates will be dropped at interim analysis and the rest three arms will be carried forward to the second stage. The characteristics of the design are presented in Table 2 for different sample sizes.

Given the response rate 0.4, 0.45, 0.45, 0.5, and 0.6 for the five arms and 91% power, if a traditional design is used, there will be nine multiple comparisons (adjusted $\alpha = 0.0055$ using Bonferroni method). The required sample size for the traditional design is 209 per group or a total of 1,045 subjects comparing a total of 500 subjects for the adaptive trial (250 at the first stage and 150 at the second stage). In cases where the null hypothesis is true (the response rates are the same for all the arms), it doesn't matter too much which arm is chosen as optimal.

Example 4: Two-stage seamless Phase I/II adaptive design for HCV trial

A pharmaceutical company is interested in conducting a clinical trial utilizing a two-stage seamless adaptive design for evaluation of safety, tolerability, and efficacy of a test treatment as compared to a standard care treatment for treating subjects with hepatitis C virus (HCV) genotype 1 infection. The proposed adaptive trial design consists of two stages of dose selection and efficacy confirmation. The primary efficacy endpoint is the incidence of sustained virologic response (SVR), defined as an undetectable HCV RNA level (< 10 IU/mL) at 24 weeks after treatment is complete (Study Week 72). This assessment will be made when the last subject in Stage 2 has completed the Study Week 72 evaluation. In both Stages 1 and 2, consider the incidence of the following primary efficacy variables of (i) rapid virologic response (RVR), that is, undetectable HCV RNA level at Study Week 4; (ii) early virologic response (EVR), that is, ≥ 2 -log10 reduction in HCV RNA level at Study Week 12 compared with the baseline level; (iii) end-of-treatment response (EOT), that is, undetectable HCV RNA level at Study Week 48; and (iv) SVR, that is, undetectable HCV RNA level at Study Week 72 (24 weeks after treatment is complete).

Stage 1 is a four-arm randomized evaluation of three dose levels of continuous subcutaneous (SC) delivery of the test treatment compared with PegIntron (standard care) given as once weekly SC injections. All subjects will receive oral weight-based

ribavirin. After all Stage 1 subjects have completed Study Week 12, an interim analysis will be performed. The interim analysis will provide information to enable selection of an active dose of the test treatment based on safety/tolerability, outcomes, and early indications of efficacy to proceed to testing for non-inferiority compared with standard of care in Stage 2. Depending upon individual response data for safety and efficacy, Stage 1 subjects will continue with their randomization assignments for the full planned 48 weeks of therapy, with a final follow-up evaluation at Study Week 72. Stage 2 will be a non-inferiority comparison of a selected dose and the same PegIntron active-control regimen used in Stage 1, both again given with oral ribavirin, for up to 48 weeks of therapy, with a final follow-up evaluation at Study Week 72. A second interim analysis of all available safety/tolerability, outcomes, and efficacy data from Stage 1 and Stage 2 will be performed when all Stage 2 subjects have completed Study Week 12. Depending upon individual response data for safety and efficacy, Stage 2 subjects will receive the full planned 48 weeks of treatment, with final follow-up at Study Week 72 (see Fig. 1).^[71]

For power analysis for sample size estimation, a total study enrollment of 388 subjects will be required (120 subjects or 30 subjects per arm for Stage 1 and 268 subjects or 134 subjects per arm for Stage 2) to account for a probable dropout rate of 15% as well as 2 planned interim analyses using the O'Brien-Fleming method. Stage 1 will enroll a total of 120 subjects divided equally among the four treatment arms to gather sufficient data to select an active dose of the test treatment to proceed to testing in Stage 2. Stage 2 will enroll an additional cohort of 268 subjects divided equally between its two treatment arms to provide a sufficient number of subjects to evaluate non-inferiority of continuous interferon delivery to standard-of-care interferon therapy, for an overall total of 306 subjects enrolled in Stage 1 and Stage 2 combined. Therefore, accounting for 15% attrition in each Stage, we expect that 164 subjects from the selected dose arms (30 from Stage 1 plus 134 additional subjects enrolled in Stage 2) and 164 subjects from the PegIntron active-control arms (30 from Stage 1 plus an additional 134 subjects enrolled in Stage 2) will need to be enrolled to meet the study objective of achieving an 80% power for establishing non-inferiority (with a non-inferiority margin of 15%) at the overall type I error rate of 5%.

Note that above two-stage seamless trial design is a combination of group sequential design, drop-the-losers design and seamless adaptive phase I/II design utilizing precision analysis (i.e., confidence interval approach) for decision-making on dose selection at the first stage. If we apply adaptive randomization for the second stage, the study design would be even more complicated. From regulatory point of view, it is important to ensure that (i) no operational biases are introduced during the conduct of the trial and (ii) the overall type I error rate is well controlled at the 5% level.

Fig. 1 Diagram of study design

Example 5: Targeted clinical trials/biomarker-adaptive trial design

Biomarker-adaptive trial design is often considered for identifying those patients most likely to respond to the test treatment under study through some validated diagnostic tests of biomarkers such as genomic markers. The process is referred to as the enrichment process in clinical trials, which has led to the concept of targeted clinical trials.^[59] As indicated by many researchers,^[60–64] the disease targets at the molecular level can be identified after completion of the Human Genome Project (HGP). As a result, the importance of diagnostic tests for identification of molecular targets increases as more targeted clinical trials will be conducted for the individualized treatment of patients (personalized medicine). For example, based on the risk of distant recurrence determined by a 21-gene Oncotype DXf0d2 breast cancer assay, patients with a recurrence score of 11–25 in the TAILORx (Trial Assigning Individualized Options for Treatment) trial sponsored by the United States National Cancer Institute (NCI) are randomly assigned to receive either adjuvant chemotherapy and hormonal therapy or adjuvant hormonal therapy alone.^[65]

Despite of different technical platforms employed in the diagnostic devices for molecular targets used in the trial, the assay falls in the category of the in vitro diagnostic multivariate index assays (IVDMIA)^[66] based on the selected differentially

expressed genes for detection of the patients with the molecular targets. In addition, to reduce the variation, the IVDMIA do not usually use all genes during the development stage. Therefore, identification of the differentially expressed genes between different groups of patients is the key to the accuracy and reliability of the devices for molecular targets. Once the differentially expressed are identified, the next task is to search an optimal representation or algorithm that provides the best discrimination ability between the patients with molecular targets and those without the targets. The current validation procedure for diagnostic device is for the assay based on one analyte. However, the IVDMIA are in fact the parallel assays based on the intensities of multiple analytes. As a result, the current approach to assay validation for one analyte may not be appropriate and is inadequate for validation of IVDMIA.

With respect to the enrichment design for the targeted clinical trials, patients with positive diagnosis for the molecular targets are randomized to receive the test drug or the control. However, because no IVDMIA can provide the perfectly correct diagnosis, some patients with positive diagnosis may not actually have the molecular targets. Consequently, the treatment effect of the test drug for the patients with targets is underestimated. On the other hand, estimation of the treatment effect based on the data from the targeted clinical trials needs to take into consideration the variability associated with the estimates of accuracy of the

IVDMIA such as positive predictive value and false positive rate obtained from the clinical effectiveness trials of the IVDMIA.

In general, there are three classes of targeted clinical trials. The first type is to evaluate the efficacy and safety of targeted treatment for the patients with molecular targets; Herceptin® clinical trials belong to this class. The second type of targeted clinical trials is to select the best treatment regimen for the patients based on the results of some tests for prognosis of clinical outcomes. The last type of the targeted clinical trials is to investigate the correlation of the treatment effect with variations of the molecular targets. Because the objectives of different targeted clinical trials vary, therefore the FDA Drug-Diagnostic Co-Development Concept Paper^[67] proposed three different designs to meet different objectives of targeted clinical trials. These three designs are given in Figs. 2–4.

Design A is the enrichment design,^[68] in which the only patients tested positively for identification of molecular targets are randomized either to receive the test drug or the concurrent control. The enrichment design is usually employed when there is a high degree of certainty that the drug response occurs only in the patients tested positively for the molecular targets and the mechanism of pathological pathways is clearly understood. Most of the Herceptin® phase III clinical trials used the enrichment design. However, as pointed out in the FDA Concept Paper, the description of test sensitivity and specificity will not be possible using this type of design without drug and placebo data in the patients tested negative for the molecular targets. Design B is a stratified randomized design and stratification factor is the results of the test for the molecular targets. In other words, the patients are stratified into two groups depending upon whether the diagnostic test is either positive or negative. Then a separate randomization is independently performed within each group to receive the test drug or concurrent control. The information of the test results for the molecular targets in Design C is primarily

Fig. 2 Design A for targeted clinical trials

Fig. 3 Design B for targeted clinical trials

Fig. 4 Design C for targeted clinical trials

used as covariates and is not involved with randomization. Sometimes, only a part of the patients are tested for the molecular targets. Design C is useful when the association of the treatment effect of the drug with the results of the diagnostic test needs to be further explored.

STRATEGIES FOR CLINICAL DEVELOPMENT

Clinical development of a new drug product is a lengthy and costly process, which includes phases I to III clinical development (prior to regulatory review and approval) and phase IV clinical development (post-approval). For life-threatening diseases or diseases with unmet medical need (rare diseases), this lengthy clinical development process is not acceptable. Such cases call for the use of adaptive design methods in clinical trials in order to shorten the development process (speed) without compromising the safety and efficacy of the drug product under investigation (validity) by maximizing the power for identify best clinical benefit of the drug product under investigation with limited number of subjects (efficiency). As a result, many adaptive design methods are developed for archiving the ultimate goals of validity, efficiency, and speed in clinical development. In practice, however, many other important factors beyond statistical components may have an impact on the development process. These factors include, but are not limited to, patient enrollment, treatment durations, and time required for regulatory review/approval.

Commonly considered strategies for the use of adaptive design methods in clinical development include, but are not limited to, adaptive dose finding, adaptive seamless phase I/II in early clinical development, and adaptive seamless phase II/III in late phase clinical development. These strategies help not only to shorten the development time in a more efficient way but also to increase the probability of success in clinical development. As an example, let us consider the development of a new drug product for a rare disease of multiple myeloma (MM) with unmet medical need. A traditional approach is to conduct a typical phase I study for identifying the maximum tolerated dose (MTD), which is often considered as the optimal dose for the late phase of clinical development. In practice, there are several options that we can run this study with several doses or dose schedules. For example, this trial can be run with parallel dose groups or sequentially with the test drug as a single or add-on agent. The traditional approach will not be able to provide the entire spectrum of the dose response of the test drug. On the other hand, if we consider an adaptive approach, it allows us to use more options at the beginning and drop some of the arms (options) if they are either too toxic or ineffective (activity too low or requires very high dose that makes the treatment very costly—biologic product may be very costly). In addition, because the treatment arms are often correlated, the information such as dose limiting toxicity (DLT) from different

arms can be synchronized using methods such as Bayesian hierarchical model.^[38]

Similar approaches can be used for phase II trials, phase I/II, or phase II/III seamless design. In this approach, the interim endpoint may be a marker such as response rate or time to disease progression. Some of the inferior arms can be dropped at interim. If some of the arms are promising, we can apply different randomization scheme to assign more patients to the superior arms (play-the-winner). In this case, not only will the total cost not increase, but additionally we will increase the chance of success because the increase of sample size for the superior treatment arms is most promising. In addition, the schedules for the trial are similar because the total number of patients remains unchanged. This adaptive design strategy can be applied to phase III trials, but with much less arms. For phase IV studies, the adaptive design can also be applied. However, the situation is different because the drug has been approved during phase IV clinical development. The focus of phase IV clinical development will be the safety rather than efficacy.

CONCLUDING REMARKS

As indicated earlier, although the use of adaptive design methods in clinical trials is motivated by their flexibility and efficiency, many researchers are not convinced and still challenge their validity and integrity.^[50] As a result, many discussions concern the flexibility, efficiency, validity, and integrity of these methods. Li^[53] suggested a couple of principles to be used when one implements an adaptive design in a clinical trial: (i) adaptation should not alter trial conduct and (ii) type I errors should be preserved. Beyond these principles, some basic considerations such as dose/dose regimen, study endpoints, treatment duration, and logistics should be carefully evaluated for feasibility.^[54] To maintain the validity and integrity of an adaptive design with complicated adaptations, it is strongly suggested that an independent data monitoring committee (IDMC) be established. In practice, IDMCs have been widely used in group sequential design with adaptations of stopping a trial early and sample size re-estimation. The role and responsibility of an IDMC for a clinical trial using adaptive design should be clearly defined. An IDMC usually conveys very limited information to investigators or sponsors about treatment effects, procedural conventions, and statistical methods with recommendations in order to maintain the validity and integrity of the study.

When applying adaptive design methods in clinical trials, the feasibility of certain adaptations such as changes in study endpoints/hypotheses should be carefully evaluated to prevent from any possible misuse and abuse of the adaptive design methods. For a complicated multiple adaptive design, an independent data monitoring committee should be established to ensure the integrity of

the study. Clinical trial simulation provide a solution, not the solution, for a complicated multiple adaptive design. In practice, deciding how to validate the assumed predictive model for clinical trial simulation is a major challenge to both investigators and biostatisticians.

In February, 2010, FDA published adrafft guidance on Adaptive Design Clinical Trials for Drug and Biologics. FDA has expressed its intention to slow down the escalating momentum behind adaptive clinical trial designs to allow time to craft better working definitions of the new models and build a better base before moving forward. Efforts are primarily directed to current issues such as the impact of protocol amendments, challenges in by design adaptations, and obstacles of retrospective adaptations as described in the previous sections. Following the draft guidance, there are several successful regulatory submissions utilizing adaptive trial designs since 2010.^[69] As a result, the draft guidance is currently being revised and under review within the FDA.

In summary, from the clinical point of view, adaptive design methods reflect real clinical practice in clinical development. Adaptive design methods are very attractive due to their flexibility and are very useful especially in early clinical development. From the statistical point of view, the use of adaptive methods in clinical trials makes current good statistics practice even more complicated. The validity of the use of adaptive design methods is not well established and fully understood. The impact of statistical inference on treatment effect should be carefully evaluated under the framework of moving target patient population as the result of protocol amendments. In practice, regulatory agencies may not realize that the adaptive design methods for review and approval of regulatory submissions have been employed for years without any scientific basis. Guidelines regarding the use of adaptive design methods and *Good Adaptive Design Practices* must be developed so that appropriate statistical methods and statistical software packages can be developed accordingly.

Lanju Zhang

Department of Biostatistics, MedImmune LLC, Gaithersburg, Maryland, U.S.A.

Abstract

This entry briefly examines clinical trials with a time-to-event primary outcome, or active survival trials, by summarizing two approaches: the treatment effect mapping approach and the optimal allocation approach.

Keywords: Censoring; Doubly biased-coin design; Optimal allocation proportion; Outcome; Treatment effect mapping.

INTRODUCTION

A survival trial is a clinical trial with a time-to-event primary outcome, such as time to death or cure. Typically, survival trials involve a limited recruitment period with staggered entry and are complicated by censoring because of losses to follow-up and other reasons, including administrative censoring. The primary outcome of a survival trial is usually analyzed using the log-rank test, or a member of the log-rank family of tests, including the Gehan test or the Peto-Peto Prentice Wilcoxon test.^[1]

Most survival trials comparing two treatments have traditionally employed equal sample sizes in each treatment arm. However, it has long been known that equal allocation does not always yield the most powerful test in survival analyses.^[2,3] Formulas that give the optimal allocation to maximize power have been derived.^[4] Equal allocation also results in half of patients being assigned to the inferior treatment arm, if one treatment is superior. To mitigate this problem, several authors have proposed adaptive randomization be used in the context of survival trials.^[5,6] In adaptive randomization, allocation probabilities are skewed away from 0.5 to favor the treatment that is performing “better” thus far in the trial. One method that has been proposed is to adapt the probabilities as a function of the current treatment effect in the trial. These probabilities can be adapted before each patient is randomized,^[5] or as groups of patients are randomized.^[4,6] Another method is to define an optimal proportion of patients to be allocated to one treatment, usually dependent on the some unknown parameters, and use a randomization procedure to target the optimal proportion. We refer to survival trials employing adaptive randomization as *adaptive survival trials*. The idea of using accruing data to assign the more favorable treatment in a survival setting can be traced to Ref. [7].

TREATMENT EFFECT MAPPING APPROACH

In the treatment effect mapping approach, one can use any treatment effect measure $S \in \Omega$ along with a function $g: \Omega \rightarrow [0,1]$, continuous, such that $g(0) = 1/2$, $g(x) > 1/2$ if $x > 0$, and $g(x) < 1/2$ if $x < 0$. Let $S(\tau-)$ be the computed treatment effect measure up to time τ . Let $X(\tau) = 1$ if a patient is randomized to treatment A at time τ , and 0 if the patient is randomized to treatment B. Let $\mathcal{F}_{\tau-}$ capture all the information on censoring and events up to time τ . Then a patient to be entered at time τ would be assigned to A with probability $E(X(\tau)|\mathcal{F}_{\tau-}) = g(S(\tau-))$,

As an example, one could use the Mantel formulation of the unnormalized log-rank statistic as S .^[5] Let $0 < \tau_1 < \dots < \tau_K$ be the ordered event times for all patients in the trial, where τ_i is the time from recruitment to event. At each event time τ_i , a 2×2 table is constructed with $\delta_i = 1$ if the event occurred on treatment A, 0 otherwise. Let n_{ji} be the number of patients in the risk set on treatment, $j = A, B$, immediately prior to the event time, and let $N_i = n_{Ai} + n_{Bi}$. Also define n_j , $j = A, B$ to be the total number randomized up to time τ , with $N = n_A + n_B$. Let $K(\tau-)$ be the number of events occurring up to τ . Then, we can let $S(\tau-) = \sum_{i=1}^{K(\tau-)} (\delta_i - n_{Ai}/N_i) / \max(n_A, n_B) \sum_{i=1}^{K(\tau-)} 1/(N - i)$. This formulation restricts $S \in [-1,1]$, where $S = 0$ means no treatment effect, so an appropriate function g would be $g(x) = 0.5(1 + x)$. Yao and Wei^[6] used the Gehan statistic as the treatment effect measure, and proposed the function

$$\begin{aligned} g(x) &= 0.5 + xr, \text{ if } xr \in [-0.4, 0.4] \\ &= 0.1, \text{ if } xr < -0.4 \\ &= 0.9, \text{ if } xr > 0.4 \end{aligned}$$

where r is a constant reflecting the degree to which one wishes to adapt the trial.

OPTIMAL ALLOCATION APPROACH

In the optimal allocation approach, one first defines an optimal allocation proportion based on an optimization problem, which usually establishes an objective function as a metric for ethical considerations and a constraint to preserve power of the test post-trial. This formulation addresses the tradeoff between ethics and efficiency.^[8] In this approach, we must use a parametric model to describe the survival/censoring distributions.

For example,^[9] consider a survival trial where patients randomized to treatment $j = A, B$ have a survival time T_j following an exponential distribution with parameter θ_j . The patients also are subject to an independent right censoring scheme. Let (t_{ij}, δ_{ij}) , $i = 1 \dots n_j$ be a random sample, where t_{ij} is a survival time and $\delta_{ij} = 1$ if the i th patient assigned to treatment j is not censored, and a censoring time and $\delta_{ij} = 0$ if the participant is censored. To test $H_0 : \theta_A = \theta_B$, we use the following statistic:

$$Z = \frac{\hat{\theta}_A - \hat{\theta}_B}{\sqrt{(\hat{\theta}_A^2/r_A + \hat{\theta}_B^2/r_B)}} \sim N(0,1),$$

where $r_j = \sum_{i=1}^{n_j} \delta_{ij}$ is the total deaths from treatment j and $\hat{\theta}_j$ is the maximum likelihood estimator of θ_j . To derive the optimal allocation in this case, assume that $\varepsilon_j = E(\delta_{ij})$ is the same for all $i = 1 \dots n_j$. Then $E(r_j) = n_j E(\delta_{Aj}) = n_j \varepsilon_j$. Minimizing the total expected hazard, we have the following optimization problem,

$$\begin{cases} \min_{n_A} n_A \theta_A^{-1} + (n - n_A) \theta_B^{-1} \\ s.t. \frac{\theta_A^2}{n_A \varepsilon_A} + \frac{\theta_B^2}{(n - n_A) \varepsilon_B} \equiv C_0 \end{cases}$$

where $n = n_A + n_B$ and C_0 is a constant. The solution is

$$\rho = \frac{n_A}{n} = \frac{\sqrt{\theta_A^3 \varepsilon_B}}{\sqrt{\theta_A^3 \varepsilon_B} + \sqrt{\theta_B^3 \varepsilon_A}}$$

One can also minimize other metrics for ethics to obtain other allocation proportions. Other models and different censoring schemes are considered in Ref. [9].

Once an optimal allocation proportion is defined, one can use a randomization procedure, such as the doubly adaptive biased-coin design,^[10] to randomize patients to the treatments such that the final proportion of patients allocated to treatment A would be very close to the target proportion ρ . During this process, the unknown parameters in ρ are replaced with their estimators based on available data. For example, the $(k + 1)$ th patient can be randomized to treatment A with the probability $p = h(N_{Ak}/k, \hat{\rho}_k)$ ^[10] where N_{Ak} is the number of patients randomized to treatment

A from the first k patients, $\hat{\rho}_k$ the estimate of ρ based on the available data from the first k patients and

$$h(x, y) = \begin{cases} 1 & \text{if } x = 0 \\ \frac{y \left(\frac{y}{x} \right)^\gamma}{y \left(\frac{y}{x} \right)^\gamma + (1-y) \left(\frac{1-y}{1-x} \right)^\gamma}, & \text{if } 0 < x < 1, \\ 0 & \text{if } x = 1 \end{cases}$$

where $\gamma \geq 0$ is a constant.

Extensive simulation studies have shown that these approaches are quite powerful.^[4-6,9] In fact, Refs. [5,6,9] report no significant losses in power and great savings in terms of expected treatment failures. Such gains in terms of individual patient experience should be attractive to both physicians and patients, and could influence recruitment and retention of patients positively.^[11] One must be wary, however, of *accrual bias*,^[12] where patients, understanding the principles behind the adaptive survival trial, will elect to enroll in the trial as late as possible, to obtain the best chance of being assigned to the better treatment.

ADAPTIVE SURVIVAL TRIALS IN PRACTICE

Planning an adaptive survival trial can be more time-consuming than planning a traditional survival trial with equal allocation. For the latter, straightforward formulas to compute requisite sample sizes and power of the log-rank test under parametric assumptions on the survival distribution are well known.^[13] Because adaptive randomization induces extra variability in the design, these formulas are not applicable. Careful simulation of power and sample size can be carried out using techniques similar to those found in Refs. [5,9]. In those papers, the authors programmed a priority queue that keeps track of patients' entry and response times. One must assume a staggered entry distribution, a delayed response distribution (that could depend on treatment assignment, response, or entry time) and a survival distribution. Programs are available from the authors upon request.

Many survival trials involve limited recruitment periods and long-term follow-up, so that patient responses are not available during randomization. Adaptive survival trials cannot be used in this context. However, the benefits of adaptive survival trials may make it attractive to extend recruitment over a longer period, so that some information may accrue to benefit future patients.

Adverse Event Reporting

Cynthia Pennise

Baxter Healthcare Corporation, New Providence, New Jersey, U.S.A.

Abstract

In order for a chemical intended for use as a medicinal product to be sold for use in humans, research must be carried out to prove that the benefits of the drug outweigh the risks associated with the drug. This entry discusses the importance of adverse event reporting, which is a crucial element in showing and understanding the side effects of a particular drug.

INTRODUCTION

In order for a chemical intended for use as a medicinal product to be sold for use in humans, research must be carried out to prove that the benefits of the drug outweigh the risks associated with the drug. Clinical studies of planned tests of the drug in people are performed following the protocols with predetermined statistical analyses planned for the safety and efficacy of the drug. These studies are conducted in a known number of patients. The results of these studies can be statistically analyzed to show that the results can be reproduced, and that the drug is useful to treat the condition and is safe in the intended population. Adverse events terminology is coded in order to group similar events and to categorize them into similar medical concepts within broad concepts for data retrieval. It is only by knowing the number of patients treated and by analyzing the adverse events reported that the safety profile of a drug can be drawn. By analyzing adverse events that occur within the test drug treatment and comparing it to a placebo-control or a known historical control, one can definitely show what side effects a drug causes.

Once a drug is marketed, the number of patients who are exposed is unknown, as is the indication that the drug was used to treat and the dose used by each patient. Unless further clinical trials are conducted for a different indication or subset of patients, information gathered from the post-marketing safety reporting cannot be utilized to request a regulatory authority to change the labeling. When a new drug is marketed, the treated population is not restricted by protocol, and there is an exponential increase in the number of patients exposed (which can only be estimated from sales volumes). New adverse events are reported that were not seen in the trials conducted by the pharmaceutical company. Postmarketing safety reporting of adverse event information is performed voluntarily. No statistical analyses can be performed on postmarketing data because of the number of patients treated being unknown as well

as the true number of occurrences of each adverse event. New adverse events can be added in the safety section of the package labeling from postmarketed use; however, no incidence for these new adverse events can be listed. This is why great care is taken in the design of clinical protocols so that appropriate claims for the efficacy and safety of a drug can be documented.

BACKGROUND OF THE DRUG APPROVAL PROCESS

The drug approval process is a long one, incorporating up to 15 years of research from the drug's inception at the chemist's bench to marketing. This process includes formulation testing, several stages of preclinical testing, and clinical testing that generally involves phases I through III clinical trials prior to marketing. If the drug survives preclinical testing, phase I studies are conducted in small populations, usually in 20–25 normal volunteers, to determine initial human safety. No formal statistical safety analysis is usually performed on these small studies because of the fact that the number of patients, or n , is small. If there appears to be no clinical safety issues after reviewing the results of the blood and urine analyses, preliminary efficacy studies are performed and are called phase II trials. These trials study the drug in the intended patient population with the target disease to be treated. The trials are small, usually 50–100 patients, and are usually single-blind studies, generally with no control arm. Although safety is looked at from a clinical perspective, it is usually not analyzed statistically. The main focus of these studies is to see if the drug appears to show some efficacy to justify additional clinical research. If efficacy appears to show a positive trend, phase III trials utilizing a placebo-control, a historical control, or a comparative control are conducted. Depending on the disease and the intended duration of human treatment (acute versus chronic use), these trials

may range from 100–200 patients treated for several days to several months, or up to several hundreds of patients to 1000 or more patients treated up to several years. Two separate controlled clinical trials are usually required for regulatory approval in order to ensure that the results can be statistically reproduced. Recently, the Food and Drug Administration (FDA) has allowed some drugs intended for critical use to be evaluated for approval utilizing a single, controlled trial. Although there are many aspects regarding the evaluation of clinical trials, the focus of this entry is on the adverse event reporting for the safety data analysis using the Medical Dictionary for Regulatory Activities (MedDRA) coding system.

CODING DICTIONARIES

The Need to Code

In order to prepare an analysis of safety data and provide any meaningful results of the safety that was seen in the trial, the safety terms, as they were reported, must be combined into similar terminology, or coded, to allow the true occurrence of similar events to be analyzed. For example, if the reported terminology for adverse events from a study includes stomach ache, stomachache, stomach pain, and pain in stomach, if analyzed as reported, there is one occurrence of each of the four terms. However, when a coding dictionary is utilized, all of the terms would be coded (depending on the dictionary used), for example, to “abdominal pain, upper” with four occurrences of this one adverse event. Combining terminology via coding dictionaries allows the safety results to be analyzed statistically and more truly reflect what is occurring in the patient population being treated with the drug product.

Common Dictionaries Utilized

There are many adverse event coding dictionaries that have been created over the years throughout the world. Some of the common ones include MedDRA,^[1] Costart,^[2] Whoart,^[3] and ICD-9.^[4] Many pharmaceutical companies have also created their own versions of adverse event coding dictionaries, an example of which is HARTS.^[5] One major problem with the existence of multiple coding dictionaries is that in addition to each pharmaceutical company choosing a dictionary to use, the regulatory authorities around the world are also using different dictionaries. This leads to many problems in companies who have to use multiple dictionaries for foreign versus domestic regulatory submissions and in regulatory authorities who have to recode the data into their dictionary of choice. This problem was the one that added to the need for the creation of the International Conference for Harmonization (ICH).^[6] The goal of this group, which represents the regulatory bodies and research-based industry in the European Union, Japan,

and the United States was to find a way to harmonize all the types of regulatory submissions for global acceptance and approval. One of the resulting guidances that arose from the formation of this group was the need for a common coding dictionary to be utilized around the world by countries in these regions. The resulting dictionary was called MedDRA. This dictionary was designed to provide a standardized coding dictionary to be utilized by industry and regulators around the world. The dictionary was made up of terminology already contained in many of the existing dictionaries, although its structure allowed greater specificity for the coding of terminology.

Medical Dictionary for Regulatory Activities

Instead of being divided into the common body systems used by previous dictionaries, MedDRA categorizes terminology into 26 System Organ Classes (SOCs). The division of terminology into these SOCs allows for the coding of medical history as well as adverse events arising from the use of both drugs and biological products. The dictionary is not currently used to code Medical Device Incidents or to code medications. The dictionary is hierarchical in that it provides vertical linking of terminology. The five-level hierarchy of the dictionary with the number of terms included in each level for version 4.1 is shown in Fig. 1.

The LLT is the place where the reported term is located. Both the British and American English spellings are used at the LLT level. Each LLT is linked to only one PT. Preferred terms represent a single medical concept and can consist of several LLTs. The dictionary utilizes the British spelling of words at the PT level and higher. Terminology utilized in statistical tables is usually represented by the verbatim term as reported and the coded term, in this case, at the PT level.

The dictionary allows for multiaxial coding, which means that certain terms at the PT level that can logically be coded to more than one SOC can be represented under more than one SOC. However, within each SOC, each PT

Fig. 1 MedDRA hierarchy

Fig. 2 Multi-axial pathway for one PT to two different SOC

is represented by only one HLT and one HLGT. Each PT has a primary pathway that must be used for the initial analysis by companies. Secondary analyses can be performed utilizing these secondary pathways. An example of the multi-axial pathway for a term is shown in Fig. 2.

The SOC are not mutually exclusive. The MedDRA dictionary also contains Special Search Categories (SSC) that contain clinical concepts that cross SOC. These SSCs allow linkage of PTs that are not necessarily equivalent or related in the hierarchy of MedDRA. These SSCs generally group PTs that are relevant to a medical issue, usually a disease or a syndrome. Preferred terms can exist in multiple SSCs. Examples of SSCs are listed in Fig. 3.

Dictionary Versions

The MedDRA dictionary is constantly updated for coding. Updates are needed because of the companies submitting requests for additions of terminology to the company managing the dictionary. Requests for changes in mapping of terms, as well as updates for dictionary consistency, also result in the need to update the dictionary. The current MedDRA Maintenance and Support Services Organization is TRW, Inc. The original MedDRA dictionary was updated four times per year; current updates are made twice per year. Major updates are indicated by an increase in the first number of the version (e.g., 4.0), with minor updates of a version indicated by an increase of the decimal (e.g., 4.1). Various pharmaceutical companies do coding of the clinical studies in many ways. One method is to initiate coding of a study in the current version of MedDRA that is being utilized at the company and to remain with the same version throughout the study. At the end of the study, the entire study can be recoded in the current version of MedDRA. An alternative way to code a clinical study is to continually update the versions as they are published. Whichever method of coding is utilized, it is important to document the version of MedDRA utilized for the coding of each study.

STATISTICAL ANALYSES FOR ADVERSE EVENT DATA

Individual Study Report

Each individual study must be statistically analyzed to show its contribution toward the approval of a drug for both efficacy and safety.^[7] Depending on the size and the objectives of the study, safety data may be analyzed with descriptive statistics (frequency, percentage, mean, and standard deviation) for most cases, or with rigorous statistical methods that provide *p*-values for comparison between different treatment groups. Note that safety data usually consist of clinical laboratory data, ECG, physical examination, and adverse events reporting. Adverse event data are one of the most, if not the most, important piece of safety data that are closely watched and reviewed by regulatory agencies.

When safety data are analyzed, it is a common practice to include all patients who received at least one dose of the study drug(s) so that the investigation of the safety profile may be executed to the greatest possible extent. As far as adverse events are concerned, in a basic summary statistics, they are presented in tables showing the incidence of each adverse event in the comparative treatment groups. Incidence is represented by showing the number of occurrences of each adverse event with the percentage of patients who experienced the adverse event. When a patient experiences a particular adverse event on more than one occasion, the patient is only counted once for that adverse event. The same is true if a patient experiences a particular adverse event that recurs and that varies in intensity (mild, moderate, or severe). The patient is counted once for that adverse event, the occurrence with the greatest severity.

Different adverse events are counted separately for the same patient. In addition to the presentation of occurrence of adverse events by treatment group, an overall cumulative tabulation of each adverse event that occurred in all treatment groups is presented. Another critical piece of the summary is the count and the percent of patients in each treatment group who experienced any adverse events. This provides a simple and condensed overall safety picture of the study drug in relation to the control/comparator drug. Presentation of the adverse events in the summary table can be performed through sorting by SOC, or by the frequency (or percent) of each SOC in decreasing order of the active treatment group. The latter presentation shows a clear trend of the occurrences of the SOCs for the test drug. Within each SOC in the summary table is the listing of the PTs that are primarily coded to that specific SOC, in alphabetical order or by decreasing order of occurrence and percent. When a large-scale multicenter trial is involved, in addition to a pooled summary of all the study centers, it may be relevant to summarize the adverse events by each individual study site. An example of a typical side-by-side presentation of the safety data is shown in Table 1.

According to the ICH guidelines, the presentation of individual patient events by drug, adverse event, severity, and relationship to treatment can be presented in Table 2.

It may be pertinent to statistically compare some SOCs that showed the highest occurrences of adverse events between and among treatment groups for a large-scale clinical trial where these SOCs are of clinical relevance for the drug product. Because there are 26 SOCs, and some SOCs may have zero count of occurrences, it would not provide any clinically meaningful information to compare every SOC. The following statistical methods are commonly used to compare adverse events within each SOC between treatment groups:

1. Chi-square test for a 2×2 summary table: this is employed in cases of comparing two treatment groups, and the number of patients with adverse events (AE) and no AE for each treatment group should be equal to or exceed 5 (preferably over 10).
2. Fisher-exact test for a 2×2 summary table: this is employed in cases of comparing two treatment groups regardless of the magnitude of the number of patients with and without AE.
3. Mantel–Haenszel test for $2 \times 2 \times q$ summary tables: this is employed in cases of comparing two treatment groups while at the same time controlling another explanatory variable (such as study sites in a multicenter study, ages grouped by at least two classes, gender, and severity of underlying disease) as the stratum, where q refers to the number of levels for the stratum. This test is statistically valid when the combined row counts are sufficiently large (for example, greater than 30).
4. Extended Mantel–Haenszel test for $2 \times r \times q$ summary tables: this is employed in cases of comparing more than two treatment groups ($r > 2$) while at the same time controlling another explanatory variable as the stratum as in Case 3 above. The case when $q = 1$ may represent a single-center clinical trial with more than two treatment groups. A realistic and conservative guideline for the modeling validity is to choose one or more cutpoints for the column for each stratum, say j ($j \geq 1$). Add the 1st through j th columns together and $(j + 1)$ th through the last columns. Then the sample size is adequate if all the cells in each new reduced 2×2 table of the q tables are 5 or more. Note that the cutpoints across all strata are not necessary to be the same.^[8]

If there is more than one treatment period in a study per protocol, the adverse events that occurred during each period should be presented separately. Also, depending on the patient population and the disease being studied, subset analyses of adverse event data can be performed. These can be performed by specific demographics, or SSC, for example.

The incidence of adverse events is evaluated for clinical significance in addition to the statistical analysis that was performed. A high incidence of a particular adverse event can often be explained by the concurrent disease state of the patients being treated. Other times there are known side effects of a particular drug class. One of the primary reasons

Table 1 Typical Side-by-Side Presentation of Safety Data

		Incidence of adverse events: number (%)		
System organ class	MedDRA PT	Treatment A (n = 25)	Treatment B (n = 25)	Total (n = 50)

Related includes adverse events that are possibly, probably, and highly probably related to the study drug.

Not related includes adverse events that are not related or remotely related to the study drug.

^aPatients are counted only once in each cell.

^bNxx represents patient ID number.

that new drugs are developed is to be able to market a drug that is effective in treating the condition and is either the first of its kind or is better than the products already available. One of the ways this superiority can be documented is by using a comparative drug as a positive control in a study and being able to show a better safety profile, or that the innovator is faster in onset or lasts longer in duration.

Integrated Summary of Safety

When filing a New Drug Application (NDA), in addition to reporting a summary of each individual study where the safety and the efficacy are analyzed for that particular study, a combined safety analysis, the Integrated Summary of Safety (ISS), must be written.^[9] The safety data from each controlled clinical trial are combined into a single data set and are analyzed to see if the safety results from the individual studies are changed when the data from all studies are analyzed together. In addition to comparing the treatment groups to one another as a whole, if there is sufficient power, subset analyses can be performed. These subset analyses depend on the patient population treated. Data can be separated and analyzed by age, sex,

race, or disease state, for example. The results of these subset analyses can provide valuable information that will eventually be included in the indications, dosing, precautions, or adverse event sections of the package insert or the Core Data Sheet. Depending on the results of the subset analysis, some adverse events may be separately described to list their incidence, for example, in pediatric or geriatric populations compared with the overall incidence for that adverse event in the total population that was treated. Safety analyses of the different disease states have provided safety results that show that the drug cannot be administered to certain patient populations (e.g., renal-impaired or hepatic-impaired patients). Within the ISS, it is sometimes useful to determine whether there is a trend when several dosing levels of the test drug are involved.

Adverse Events as Secondary Endpoint

In addition to proving that a drug is effective, for certain disease states, there are certain known side effects, or sequelae, that occur in the usual course of the treatment. If these sequelae are known in advance of protocol design, the study can be designed to show that the study drug

is “safer” than other products available by resulting in a lower incidence of the known side effects. The protocol should be written to include detailed statistical approach to this secondary analysis.

CONCLUSION

The safety of a drug product is important for its approval for marketing. Careful planning of the clinical trials for study design is important. Analysis of adverse events can be performed as a basic necessity to show the safety of a drug product. In some cases, adverse event data can also be analyzed as a safety endpoint in order to provide data for labeling claims. This is one of the many reasons to be sure that your statisticians are well informed about the disease and the patients being treated when the protocol is written to ensure sufficient power for labeling claims.

Abstract

In this entry, we review the background for the alpha spending function, give an overview of classic group sequential methods, and focus on the alpha spending functions.

Keywords: Alpha spending function; Clinical trial; Data monitoring; Group sequential analysis; Interim analysis; Type I error.

INTRODUCTION

Clinical trials have become the major standard over the past three decades for evaluating new therapies and medical interventions. In the majority of studies, accruing data are monitored and analyzed at intervals by the sponsor or an independent data monitoring committee. Any repeated significance tests will inflate the type I error probability and lead to false claims of a treatment benefit even when one does not exist. Group sequential methods were introduced in the late 1970s in order to control the type I error; however, they require predetermination of the number of interim analyses and equal increments of information between looks. A more flexible approach was introduced by Lan and DeMets,^[1] which eliminated the constraints of the group sequential methods by introducing a spending function for alpha. In this entry, we review the background for the alpha spending function, give an overview of classic group sequential methods, and focus on the alpha spending functions.

BACKGROUND

Interim Analysis

In the ICH Guideline E9 (Statistical Principles for Clinical Trials), an interim analysis is defined as any analysis intended to compare treatment arms with respect to efficacy or safety at any time prior to the formal completion of a trial.^[2] Generally, the use of an interim analysis can aid in decision making on: (a) early stopping of a clinical trial for overwhelming efficacy, (b) early stopping for futility, and (c) modification of certain aspects of the trial design mid-course such as, sample size re-estimation in order to have sufficient power. In conducting interim analyses, we carry out repeated significance tests, which

inflate the overall significance level, and thus increase the chances of a false positive claim.^[3] Several group sequential methods^[4–7] have been developed for use to preserve the overall significance level alpha.

STANDARD GROUP SEQUENTIAL METHODS

Although not originally described as a group sequential procedure, a method described by Haybittle^[6] in 1971 and later supported by Peto et al.^[7] has often been used. For each analysis, Haybittle proposed a very conservative analysis critical value for all interim analyses (e.g., ± 3.0 or ± 3.5) such that the type I error increases almost negligibly. This implies for all practical purposes, one could use the usual 5% critical value of ± 1.96 at the last scheduled analysis should the trial continue that far. More formally:

$$\begin{aligned} C(k, \alpha) &= C_{H-P}, & k = 1, \dots, K-1; \\ C(k, \alpha) &= Z_{1-\alpha/2}, & k = K. \end{aligned}$$

In the above equations, the subscript H-P indicates Haybittle–Peto, K is the total number of analyses, and α is the overall significance level for a study. Obviously, a disadvantage is the somewhat ad hoc choice for the interim testing levels. Another disadvantage is the uncertainty regarding the overall probability of type I error.

Pocock^[4] more formally introduced the term “group sequential” with his work in 1977, modifying proposals by McPherson and Armitage. His method uses a constant boundary in order to make a decision about whether or not to reject the null hypothesis and to control the overall significance level alpha. Here:

$$C(k, \alpha) = C_p(K, \alpha), \quad k = 1, \dots, K.$$

His proposal uses up the overall significant level equally at each time point that an analysis is undertaken.

O'Brien and Fleming^[5] proposed an alternative method in 1979, which uses a monotone-decreasing boundary, against which the test statistic is compared to decide whether or not to reject the null hypothesis. In this case:

$$C(k, \alpha) = C_{O-F}(K, \alpha) \sqrt{(K/k)}, \quad k = 1, \dots, K.$$

It starts with a very stringent nominal significant level, making it very difficult to stop the trial early on, but ending with a nominal significant level very close to the overall significance level.

Fig. 1 shows the comparison of the three group sequential methods using $\alpha = 0.05$ with a two-sided standard normal test statistic Z and four interim analyses. The three methods have very different stopping boundaries. The O'Brien–Fleming method is unlikely to lead to stopping in the early stages. Later on, however this procedure leads to a great chance of stopping prior to the end of the study compared to the other two methods. Both the Peto and O'Brien–Fleming methods avoid the awkward situation of accepting the null hypothesis when the statistic at the end of the trial is much larger than the conventional critical value (i.e., 1.96 for a conventional two-sided significance level). It is not obvious what criteria should be used to select from among the various rules; however, of the three methods described, the O'Brien–Fleming more closely mimics the behavior of many data monitoring committees, who are usually conservative at the beginning stage of the trial when they will require a greater level of evidence to persuade them to stop a study early.

Fig. 1 Comparison of three group sequential methods using $\alpha = 0.05$ with a two-sided standard normal test statistic Z

ALPHA SPENDING FUNCTIONS

Origin of Alpha Spending Function

The practical problems in implementing the standard sequential methods are that first they require a prior specification of the number of interim analyses needed for a clinical trial, and secondly they require that the interim analyses must be equally spaced so that the amount of information which accrues for each interim analysis is uniform. These may actually cause difficulty and inconvenience in conducting a clinical trial. For example, the DSMB (Data and Safety Monitoring Board), which is usually responsible for conducting the interim analysis, may not be able to have all its members available at a specific time point when additional data has been accrued. Lan and DeMets proposed the alpha spending function approach to overcome those problems by extending the group sequential concept to a very flexible method that controls the overall alpha level, while allowing for the number and exact timing of the interim analyses to remain unspecified *a priori*.^[1] If a spending function is selected in advance of the study, starting according to a desired boundary, then interim analyses can be conducted as needed. Even determining the frequency of analyses based on emerging trends negligibly affects the false-positive error rate, especially for conservative boundaries.^[28]

The spending function of Lan and DeMets was developed in the context of designs that do not allow early stopping with rejection of the alternative hypothesis. Pampallona, Tsiatis, and Kim^[14] proposed an adaptation, whereby the total probability of the type II error (β) can be incorporated after successive looks. For this reason the alpha spending function has also been referred to as the use function,^[8] spending function,^[11,12] and the error spending function.^[13] Here we will use the term alpha spending function.

Concept of Alpha Spending Function

Slud and Wei^[15] discussed the idea of distributing the overall significance level alpha (α) to each interim analysis by using the increments of α , say, $\alpha_1, \dots, \alpha_K$, where $\alpha_1 + \dots + \alpha_K = \alpha$, and K is predefined as the total number of analyses in the study. However, no particular function was suggested or proposed to distribute the α , although they recommend that the sequence $\alpha_1, \dots, \alpha_K$ be increasing. Lan and DeMets^[1] first suggested the alpha spending function concept. The function $\alpha^*(t)$ describes the rate at which the total significance level alpha is to be spent or used as a continuous function of information fraction t . In the context of a clinical trial, t indicates how much of the trial has been completed in terms of the accumulated information, and thus indicates how much of the allowable type I error should be allocated.^[10] The $\alpha^*(t)$ generates the cumulative

significance level “used up” after the current analysis and relates the sequence of nominal significance levels through a Brownian motion process.^[1]

Derivation of the Original Spending Function

The original boundary suggested by Lan and DeMets was proposed because of its similarity to the O’Brien–Fleming boundary. The derivation of that spending function is presented here to help the reader understand the process. This is described for a one-sided test, but it is easy to generalize to a two-sided test by replacing α by $\alpha/2$.

Let $\{B(t), 0 \leq t \leq 1\}$ be a standard Brownian motion process, and let τ be the first exit time across the boundary. Here let’s consider a horizontal boundary $b(t) = z_{\alpha/2}$, so if we assign $\alpha^*(t) = \Pr(\tau \leq t)$, then it follows that:

1. $\alpha^*(0) = 0$;
2. For $0 < t \leq 1$,

$$\begin{aligned}\alpha^*(t) &= \Pr(\tau \leq t) \\ &= \Pr(|B(t)| > b(t)) \\ &= \Pr(|B(t)| > Z_{\alpha/2}) \quad (\text{because } b(t) = Z_{\alpha/2}) \\ &= \Pr(|B(t)/\sqrt{t}| > Z_{\alpha/2}/\sqrt{t}). \\ &= \Pr(|Z| > Z_{\alpha/2}/\sqrt{t}) \quad (\text{because } B(t) \sim N(0, t), \\ &\quad \text{then } B(t)/\sqrt{t} \sim N(0, 1)) \\ &= 2\left(1 - \Phi\left(Z_{\alpha/2}/\sqrt{t}\right)\right) \\ &\quad (\text{where } \Phi \text{ is the standard normal function}) \\ &= 2 - 2\Phi\left(Z_{\alpha/2}/\sqrt{t}\right).\end{aligned}$$

So, $\alpha^*(t)$ is strictly increasing in t ; and $\alpha^*(1) = \alpha$, which is equal to the prespecified significance level.

Assume that $B(t)$ be observed only at discrete time points $t_i, i = 1, \dots, K$, with $0 < t_1 < \dots < t_K = 1$. Assign an accumulated boundary crossing probability $\alpha^*(t_1)$ to the point t_1 , by defining b_1 to satisfy

$$\begin{aligned}\Pr\{B(t_1) > b_1\} \\ &= \Pr\{\tau \in [0, t_1]\} \\ &= \alpha^*(t_1)\end{aligned}$$

For $i = 2, \dots, K$,

$$\begin{aligned}\Pr\{B(t_j) < b_j, j = 1, \dots, i-1; B(t_i) > b_i\} \\ &= \Pr\{\tau \in (t_{i-1}, t_i)\} \\ &= \alpha^*(t_i) - \alpha^*(t_{i-1})\end{aligned}$$

Once we allocate the alpha to the spending function, then the next step is that we need to calculate the nominal boundary $(b_1, \dots, b_K)$ against which the observed test statistic can be compared to conduct the statistical hypothesis testing.

For $i = 1$,

$$\begin{aligned}\Pr\{B(t_1) < b_1\} \\ &= 1 - \Pr\{B(t_1) > b_1\} \\ &= 1 - \alpha^*(t_1) \\ &= 1 - \left(2 - 2\Phi\left(Z_{\alpha/2}/\sqrt{t_1}\right)\right) \\ &\quad (\text{plug in the function we derived above}) \\ &= 2\Phi\left(Z_{\alpha/2}/\sqrt{t_1}\right) - 1.\end{aligned}$$

From standard Brownian motion, we know that $B(t_1)/\sqrt{t_1} \sim N(0, 1)$, then

$$b_1 = \sqrt{t_1} \Phi^{-1}\left\{2\Phi\left(Z_{\alpha/2}/\sqrt{t_1}\right) - 1\right\}.$$

For $i = 2, \dots, K$, evaluation of b_i can be done by using numerical integration,^[3,11,13] because from the Brownian motion process, we know that the $B(t_1), \dots, B(t_K)$ jointly follow a multivariate normal distribution.^[16,17] The algorithm for the numerical integration can be found in references.^[3,11,13]

Note the above calculation process of the boundary depends only on the functional form $\alpha^*(t)$ and information $t_1, \dots, t_i$, therefore we do not need to know K (the total number of analyses) or $t_{i+1}, \dots, t_K$ (the future time points). Now we are in a position to use this derived function and the corresponding evaluated boundary values to conduct an interim analysis without the necessity of either knowing K (the total number of analyses) or the equal spacing of information t_i ; indeed the points $t_1, \dots, t_i$ need not be equally spaced.

TYPES OF ERROR SPENDING FUNCTIONS

The above error spending function was the first one derived from the standard Brownian motion process as we have shown, and is only one of many functions that have been proposed or developed since then. Other approaches defined in the original paper by Lan and DeMets^[1] were:

1. Pocock-type

$$\alpha_2^*(t) = \alpha \ln[1 + (e-1)t], \quad 0 < t \leq 1$$

It can approximate the standard group sequential method Pocock boundary.

2. Uniform function

$$\alpha_3^*(t) = t, \quad 0 < t \leq 1$$

It spends alpha uniformly over the information fraction t .

Additional functions introduced subsequent to this include:

3. ρ [Kim and DeMets^[8]]

$$\alpha_4^*(t) = \alpha t^\rho, \quad 0 < t \leq 1$$

Special mention was made of $\rho = 2$ and $\rho = 3/2$, which reduce the likelihood of the embarrassing situation of having a significant result at the k th analysis and a non-significant results at the $(k + 1)$ th analysis.

4. Segmental function [Li and Geller^[18]]

$$\alpha_5^*(t) = 0.8\alpha t | \{0 \leq t \leq 0.75\} \\ + (1.6\alpha t - 0.6\alpha) | \{0.75 < t \leq 1\}$$

They noted that by using the strictly convex functions, such as that by Kim and DeMets,^[8] the analysis times will be severely restricted, especially near the end of a trial, where frequent monitoring is often desirable.^[19] They proposed the above spending function to have the property of the uniform use of 60% of the alpha during the accrual of 75% of the information and 40% of alpha reserved for the last 25% information.

5. One-parameter Gamma Family [Hwang, Shi, DeCan^[9]]

$$\alpha_6^*(t) = \alpha(1 - e^{-\gamma t}) / (1 - e^{-\gamma}), \quad \gamma \neq 0$$

$$0 < t \leq 1,$$

$$\alpha_6^*(t) = \alpha t, \quad \gamma = 0, \quad 0 < t \leq 1.$$

It includes members similar in shape to the spending functions of Pocock ($\gamma = 1$) and O'Brien–Fleming ($\gamma = -4$). Negative values of γ yield convex spending functions that increase in conservatism as γ decreases, while positive values of γ produce convex spending functions that increase in aggressiveness as γ increases.

6. Other types include the unifying family of Kittleson and Emerson^[20] for the mean statistic and the Wang–Tsatis delta family,^[21] which includes standard group sequential methods such as Pocock's and O'Brien–Fleming's methods as special cases.

Generally speaking, the Pocock-type and the O'Brien–Fleming-type are two extreme cases. The former is an aggressive method in terms of spending alpha heavily at the early stage of the trial, while the latter is a conservative method because it spends a very little at the beginning but reserves the majority of alpha for later stage of the trial.

CHOICE OF ALPHA SPENDING FUNCTION $\alpha^*(t)$

Because there are many types of alpha-spending functions, we provide some guidance below:

The function should be an increasing function $\alpha^*(t)$ with $\alpha^*(0) = 0$, and $\alpha^*(1) = \alpha$ to construct the boundary

and to enable the control of the overall significance level for a study.^[11] A strictly convex $\alpha^*(t)$ is recommended in general.^[8,10,15,19] Using steadily increasing sequence of $\alpha^*(t_k) - \alpha^*(t_{k-1})$ so that the resulting boundary values $b_k / \sqrt{t_k}$ decrease. Using steadily decreasing boundary values will be unlikely to result in an embarrassing possibility of non-significant result at t_{k+1} when a decision to stop the trial with significant results at t_k , was deferred.^[15] A situation like this may result in the DSMB deciding to ignore the boundary being crossed and is called “overruling.”^[22]

When short-term effects are of interest in a clinical trial with planned interim analyses, then early stopping would be desirable, so $\alpha^*(t)$ with a smaller expected stopping time (e.g., Pocock-type α spending function) has a good chance of an early rejection of the null hypothesis if the alternative hypothesis is true.^[10] On the other hand, when long-term effects are of interest, use more convex $\alpha^*(t)$ that would generate boundaries similar to O'Brien and Fleming boundaries. By doing so, we will use very little alpha at the early interims and save the majority of the alpha for near the end of the trial.

INFORMATION FRACTION t

Once we've made a choice about the alpha spending function, then the next important step is to decide how to define operationally the information fraction t before the trial starts. Obviously, even if we use the same alpha spending function, different definitions of t would lead to different boundary values. Here we give some guidance. In general, the information fraction t should be defined as the amount of information provided by the accumulated subjects up to the current analysis, divided by the amount of total information planned or expected for the study.^[10] For comparing means or proportions, t is approximated by the observed sample size divided by the expected maximum sample size (n/N). For survival data, t may be approximated by the number of observed events (for example, deaths in a clinical oncology trial) divided by the total expected number of events (e/E); t may also be approximated by the time up to current analysis, divided by the total planned duration for the study (t/T). The former is called maximum information design and the latter maximum duration trial. For repeated measurements data, a definition of t in the context of the linear mixed model was provided by Lee and DeMets.^[23]

COMPUTING SOFTWARE

Because computation for using the alpha spending function normally requires complex numerical integration, several software packages have been developed and are available for sequential analyses. The software EaSt (version 3.1 or higher) is commercially available from Cytel Corporation, Cambridge, Massachusetts. LANDEM

is a Fortran-based program publicly available from the Department of Biostatistics, the University of Wisconsin, Madison, Wisconsin, and its detailed usage with examples has been published.^[11] R is free software widely used in the statistical circle around the world and it has a function called the `ldBands()` function which can carry out alpha spending function calculations.^[24] PEST is commercially available from the MPS unit, the University of Reading, United Kingdom, featuring the triangular sequential test.^[25] The S + Seq Add-on package for S-plus is commercially available from the Insightful Corporation, Seattle, Washington.^[13]

APPLICATION OF THE ALPHA SPENDING FUNCTION

Design of an Interim Trial Using Alpha Spending Function

The alpha spending function has been applied in clinical trials with planned interim analyses to aid decision making on early stopping in a number of different scenarios:

1. Stop early for efficacy only, i.e., to reject H_0 on a one-sided test.
2. Stop early for safety only, i.e., to reject H_0 on a one-sided test.
3. Stop early for futility only, i.e., to reject H_1 on a one-sided test.
4. Stop early for efficacy or safety, i.e., to reject H_0 on a two-sided test.
5. Stop early for efficacy or futility, i.e., to reject H_0 or reject H_1 on a one-sided test.
6. Stop early for efficacy, safety, or futility, i.e., to reject H_0 or reject H_1 on a two-sided test.
7. Stop early for futility only, i.e., to reject H_1 on a two-sided test.

In the above, scenarios 1 and 2 are essentially the same in terms of the methodology except that the statistic in 1 is related to efficacy, e.g., the reduction in viral load in an AIDs trial, while the statistic in 2 is related to safety, such as detecting an increase in the number of adverse events for a new compound compared to an approved drug in the same class.

Scenario 4 is a two-sided test, which is actually often used in clinical trial practice.

In scenario 3, this use is usually referred to as beta spending function instead of alpha spending function because the lower futility stopping boundary (critical values) is chosen to maintain the nominal type II error rate,^[14] i.e., the spending function is chosen to control the rate of spending type-II error. Monitoring for futility is usually combined with a test for benefit as in scenario 5, and this approach is becoming more popular in clinical trial practice. Scenario 6 is usually called a two-sided test with an inner wedge,^[13] which is used to accept H_0 . Scenario 7 is sometimes called “only an inner wedge,” which is rarely used in practice.^[13] The choice between a one-sided and a two-sided test is based on the parameter of interest. In some cases, a one-sided alternative is appropriate because departures from H_0 in the other direction are either implausible or impossible. In other cases, the parameter of interest may lie on either side of H_0 , but the alternative is chosen in the one direction in which departures from H_0 is of clinical interest. Obviously, a one-sided test tends to reduce the expected sample size.^[13]

Here we present examples for the commonly used scenarios 4 and 5. The other scenarios are relatively easy extensions of 4 and 5, so they are not illustrated here.

For scenario 4, let's design a hypothetical phase III, randomized, double-blind, active-controlled, clinical oncology trial to compare the efficacy of the new investigational drug monotherapy against that of the standard therapy to treat a specific cancer in adult patients. Three interim analyses are to be planned for this trial. The primary efficacy endpoint for this trial is progression free survival (PFS); and from literature, median PFS for standard therapy is 4 months and we expect that the median PFS for the new drug will be improved by 50% to 6 months. Patients are to be randomly assigned to a new investigational drug and to a standard therapy in a 2:1 fashion to allow more patients to receive the promising new therapy. We will use the O'Brien–Fleming-type spending function to design this trial. Table 1 shows the details we need given a two-sided, $\alpha = 0.05$ and 90% power, illustrated graphically in Fig. 2. The computation was carried out using the software EaSt 3.1.

For scenario 5, we will use the example presented by Pampallona, Tsiatis, and Kim,^[14] which was a typical, randomized, two-arm trial comparing a control to an

Table 1 Design of an Interim Trial Using O'Brien–Fleming-Type Spending Function

Look	Number of events	Information fraction (t)	Hazard ratio	P -value	Lower boundary (Z)	Upper boundary (Z)
1	70	0.25	0.34	0.0001	−4.33	4.33
2	140	0.50	0.59	0.003	−2.96	2.96
3	211	0.75	0.71	0.018	−2.36	2.36
4	281	1.00	0.78	0.044	−2.01	2.01

Fig. 2 Design of an interim analysis using O'Brien-Fleming-type function with $\alpha = 0.05$, 90% power and a two-sided test

experimental arm on the basis of a one-sided normally distributed statistic (Z). It's assumed that under the alternative hypothesis, the effect size (mean difference divided by standard deviation) equals 0.25. Three interim analyses (a total of 4 looks) were planned for this study. Patients were to be randomly assigned to the two groups in a 1:1 fashion. The O'Brien-Fleming-type spending function was used to design this trial. Table 2 shows the details we need given a one-sided $\alpha = 0.05$ and 90% power—this again is illustrated graphically in Fig. 3. As shown here, the use of a futility boundary allows us to stop the study early when the treatment is not working, which leads to a smaller expected sample size under the null hypothesis.

Analysis of an Interim Trial Using the Alpha Spending Function

For illustrative purposes, we will describe the approach to the Beta-Blocker Heart Attack Trial (BHAT). BHAT was a randomized double-blind, multicenter trial to evaluate the effect of propranolol in reducing mortality in patients who had recently suffered a myocardial infarction.^[26,27] The O'Brien and Fleming-type α spending function was used. The statistical analysis of time to event data was carried out using a log-rank statistic. For this study, the calculated

Fig. 3 Design of an interim analysis for simultaneous efficacy and futility using O'Brien-Fleming-type function with $\alpha = 0.05$, 90% power and a one-sided test

log-rank statistic for each interim analysis is shown in the last column of both Tables 3 and 4. Two scenarios of designs are shown here.

1. As a maximum information trial: if the study was planned with total amount of information $D = 400$ deaths, the information fraction at each interim analysis would be the number of deaths up to that point divided by D (d/D). After the information fraction is obtained, then a boundary value (Z) can be computed using the O'Brien and Fleming-type α spending function (see Table 3).
2. As a maximum duration trial: if the study was planned with duration 48 months, the information fraction for each analysis would be the time up to current analysis divided by the $T(t/T)$. After the information fraction is determined, then a boundary value (Z) can be computed using the O'Brien-Fleming-type α spending function (see Table 4).

Fig. 4 shows the interim analysis for the BHAT trial using the O'Brien-Fleming-type function. Obviously, the two boundaries are very different, although the stopping point for this example happens to coincide at the sixth interim analysis point, where the observed log-rank statistic

4	28	0.58	2.74	2.30
5	34	0.70	2.49	2.34
6	40	0.83	2.27	2.82

**Fig. 4** Interim analysis for the Beta-Blocker Heart Attack Trial (BHAT) trial using the O'Brien–Fleming-type function

($Z = 2.82$) exceeded both boundaries at this interim analysis time point. However, we should bear in mind that generally that may not be the case. Therefore, it is critical to pre-specify how to define the information fraction t as well as the predetermined spending functional form.

Some Issues in Using the Alpha-Spending Functions

With the application of alpha-spending functions into clinical trials, questions involving interim analysis have been arising, such as how to deal with overruling,^[22] changing monitoring frequency,^[28] and multiple primary endpoints in clinical trials.^[29] For instance, because the

statistical decision rule is only one of the factors for consideration in making a final decision about whether to stop or continue a trial based on a certain time point interim analysis, the DSMB may decide to continue a trial even when the statistical boundary has been crossed. This is called overruling. In the case of overruling, we may buy back the previously spent probability to be respent or redistributed at future looks.^[22] Sometimes, the frequency has to be increased due to emerging trends. In this case, the probability of type I error will no longer be preserved exactly, but simulation results show that the changing frequency of interim analyses has a negligible inflation of the type I error^[28] for the common spending functions such as O'Brien–Fleming type. Recently, a global alpha spending function has been proposed for a trial with multiple primary endpoints.^[29] Asymmetric boundaries are also common and allow for stopping rules for both efficacy and safety, and to allow for early stopping for futility.^[14] Other issues include how to provide valid parameter estimates and confidence intervals at the end of a study, allowing for any “shrinkage” to the estimates that may have occurred because of the interim analyses. The detailed expositions of these issues are beyond the scope of this entry. Interested readers may refer to the respective reference for details.

CONCLUSION

The alpha spending function is a practical tool to control the rate at which the overall type I error alpha is to be spent or used as a continuous function of information fraction. It is very flexible. The total number of interim analyses need

not be prespecified, and the information fraction need not be equally spaced. The users can also specify their own spending function. Implementation is made easy because of the availability of computing software.

ACKNOWLEDGMENTS

We would like to thank Parke-Davis Pharmaceutical Research Division of Warner-Lambert Company for initial support of my work on this field. We want to express appreciation to Eric Yan, Nai-tee Ting, and Randy Allred for valuable suggestions in the preparation of this manuscript. Our continued motivation in this field would not be possible without collaboration with our Pfizer clinical colleagues on applications of the alpha-spending functions in clinical trials practice. Abstract

Two- and threefold rules and various parametric and nonparametric methods have been applied to the Ames test data. This article will review these analysis methods and discuss the design, statistical analyses, and interpretation of results of the Ames test.

Keywords: In vitro assay; In vivo assay; Safety profile.

INTRODUCTION

Genetic toxicology tests are among the early studies conducted to assess the safety profile of a compound. A battery of tests, each assessing a different genetic endpoint, is typically performed to thoroughly evaluate a given compound because no single test is capable of detecting all mutagens. The tests are designed to determine whether the compound can interact with DNA and lead to the production of gene mutations or chromosomal breakage. Some tests can also detect compounds that interact with components of the mitotic spindle apparatus. The detection of mutagens is important because they may also be either teratogens or carcinogens. Of a battery of short-term genetic assays, the *Salmonella typhimurium*/microsome test developed by Ames et al.^[1,2] is the most commonly used genotoxicity test. Two- and threefold rules and various parametric and non-parametric methods have been applied to the Ames test data. This article will review these analysis methods and discuss the design, statistical analyses, and interpretation of results of the Ames test. “Background” includes information pertaining to the relevance of the Ames test to the toxicology safety profile. The “Design” section describes the basic design of the test. The section “Analysis Methods for Ames Test Data” provides a review of some analysis methods employed for the evaluation of the mutagenicity of a compound. In the “Discussion” section, we discuss the methods reviewed and some important issues in the evaluation of mutagenicity based on Ames test results, and in the last section we draw concluding remarks to summarize this article.

Notes: Adapted from Hoffman, W.P. In *Design and Analysis of Animal Studies in Pharmaceutical Development*; Chow, S.C.; Liu, J.P.; Eds.; Marcel Dekker: New York, 1998, 357–372.

BACKGROUND

This section presents a brief summary of why the Ames test was developed and how this assay is conducted. The procedure for conducting the Ames test is described without too much detail. This section is not intended to provide enough information to conduct the assay; it is intended to provide readers with a general understanding of how the responses are obtained and thus leads naturally into the following sections on the design and statistical methods employed for analysis of the test data.

WHY THE AMES TEST

When developing a compound for commercial purposes, one has to establish its safety profile. *In vivo* animal and *in vitro* cell culture tests are designed to serve this purpose. In general, the testing includes acute toxicity tests in rodents, genetic toxicity tests, developmental toxicity tests, general animal toxicity tests from 30 days up to 1 year in duration, and lifetime carcinogenicity tests in rodents. Of these general tests, which are needed to demonstrate the safety of a compound and to ensure its registration worldwide, the most costly and time-consuming test is the carcinogenesis bioassay in rodents. Assays for genotoxicity were initially developed in an attempt to predict in a shorter time frame the eventual outcome of the bioassay. The basic premise revolved around the somatic theory of carcinogenesis, which suggested that mutational events were causative factors in the development of cancers. Additionally, there was evidence that mutagenic events were associated with embryonic mortality, birth defects, and genetic disease. Therefore, the use of genotoxicity tests seemed to have broad

application in the overall safety assessment. Although bacterial mutation tests had been used since the 1950s, they were not efficient in the detection of compounds acting by various mutagenic mechanisms. Efforts by Bruce Ames and his colleagues at the University of California, Berkeley, to develop a more efficient bacterial screening system culminated in 1971 with the test that now bears his name. Despite the test's utility, it was realized that bacteria are not mammalian cells and that the organization of the genetic material was different so that other short-term mutagenicity tests would be required to ensure the detection of the majority of rodent carcinogens.^[3] Although over 200 mutagenicity tests have been developed, few have been well validated, and current regulatory requirements for product registration include only a battery consisting of two to four tests of the seven most thoroughly validated standard tests.^[4-6] Of these required tests, the Ames test is the most commonly used and for this reason alone merits discussion.

THE AMES TEST

The Ames bacterial mutation test is an in vitro assay in that it uses bacterial cells grown on agar contained in petri plates. Typically, the *Salmonella typhimurium* bacterial tester strains TA1535, TA1537, TA98, and TA100 and an *Escherichia coli* tester strain WP2uvrA are used in the Ames test. Although WP2uvrA was added to the bacterial test system after the Ames test was developed, it is handled the same as the four *S. typhimurium* strains in all aspects of the conduct and analysis of the experiment. Therefore, in this article, Ames test will refer to the assay of the four *S. typhimurium* strains and the *E. coli* strain. For each strain of the bacteria, a mixture of the proper amounts of three ingredients is first prepared in a tube. The three ingredients are (i) from 10–100 million bacterial cells from a particular strain; (ii) a compound, which can be a test article, negative control, or positive control; and (iii) minimal agar, which includes trace amounts of histidine, tryptophan, and biotin and may or may not contain S9 mix. See Fig. 1. The mixture is then poured into a plate containing a layer of solidified minimal agar for the growth of revertant colonies. Some compounds are not directly mutagenic in vivo but are metabolized to a compound that is. Therefore, all in vitro genotoxicity tests, including the Ames test, are conducted so that cells are exposed to the test article both in the presence and in the absence of an exogenous metabolic activation system. This metabolic activation system consists of a postmitochondrial supernatant (S9) of homogenized liver tissue from rats. This cell-free extract contains a variety of drug-metabolizing enzymes. The S9 is supplemented with cofactors, salts, and a buffer system collectively known as S9 mix.

Fig. 1 Description of the conduct of the Ames test

Histidine and tryptophan are amino acids essential for the growth of the tester strains of *S. typhimurium* and *E. coli*, respectively. The Ames tester strains contain mutations in the genes that allow normal bacteria (prototrophs) to manufacture their own histidine or tryptophan. The tester strains are dependent upon the inclusion of the amino acids into the minimal agar to support their growth. These mutant bacteria are called auxotrophs. The Ames test is often referred to as a “reverse” mutation assay because what is measured is the reverse mutation rate from histidine/tryptophan dependency (auxotrophy) to histidine/tryptophan independence (prototrophy). Bacterial cells that have undergone the reverse mutational event are called “revertants.” Trace amounts of histidine and tryptophan are provided at the start of the experiment to sustain the bacterial cells at the beginning and thus to allow the possible expression of reverse mutation events later. After a 48-hour incubation period, the revertant cells will form visible colonies, which are counted. Because reverse mutation may occur without treatment with a mutagen, a negative control is always included in the assay to account for the spontaneous reverse mutation rate. If a compound is not a mutagen, then one would not expect a large increase in the number of revertant colonies compared to the number of spontaneous revertant colonies in the negative control. Therefore, the number of revertant colonies is the response evaluated to determine the mutagenic effect of a test article. A significant increase in revertant colonies on the compound-treated plates is an indication of a positive response for bacterial mutation.

DESIGN

The Ames test procedure is rather strictly defined for regulatory purposes.^[7-9] The assay is typically conducted both with and without metabolic activation for each of the five bacterial strains. For each bacterial strain, five

or more concentration levels of a compound and proper concentration levels for the negative and positive controls are determined by scientists. A positive control is required for the validity of the assay but is not included in the evaluation of the mutagenicity of a compound. A negative control is needed to account for spontaneous reverse mutation in the evaluation of the mutagenicity of the test article. Historical control data are useful for further evaluation of positive effects associated with a compound. Each dose level is tested in triplicate, and each of the triplicate plates is prepared independently. Therefore, if five concentrations are selected for each bacterial strain, then a total of 50 sets of triplicate data from the compound (five concentrations, two types of activation, and five strains of bacteria) and 10 sets of triplicate data from each of the negative control and positive control are the results of the assay.

Because the purpose of the Ames test is to evaluate the mutagenic effects of a compound, a suitable selection of the concentration levels of a compound for testing is essential. Logarithmically spaced concentration levels are determined by scientists in an attempt to capture an increasing trend in the response. However, if the concentration of the compound is too high, then one would expect a decrease in the number of revertant colonies as a result of toxicity. For determination of the concentration levels for the Ames test, a compound is initially assayed over a wide range of concentration levels up to 5,000 µg/plate for each bacterial strain. Based on the preliminary results, five to seven concentration levels are then selected for a definitive assessment. The highest concentration may be very close to the toxic level. In the absence of toxicity, a top concentration of 5,000 µg/plate is used in the definitive assessment of mutation induction.

ANALYSIS METHODS FOR AMES TEST DATA

Proper analysis methods should account for various sources of variability in the response. Therefore, one needs to identify different sources of variability in the assay data before considering the analysis. Based on the variability and some assumptions, we discuss various statistical and nonstatistical methods for the analysis of revertant colonies obtained from the Ames test. Edler^[10] and Mahon et al.^[11] provide a good overview of statistical methods for the Ames *Salmonella* test. For a more recent review of statistical methods, see Lin.^[12] Here we will begin the discussion with some basic information on data in the next section. Then selected methods will be discussed to bring about different approaches for the analysis of Ames test data. The methods discussed in the subsequent sections are modified two- and threefold rules, non-parametric methods, and parametric methods.

UNDERSTANDING DATA

What is the distribution of the number of revertants from the Ames test? Before suggesting an answer, let us first understand the data and try to identify various sources of variability in it. For each replicate plate, a separate minimal agar mixture of the selected strain of bacterial cells, the test article, and a solution of histidine, tryptophan, and biotin is made in a tube. Therefore, the numbers of revertants from the triplicate plates are independent. Because auxotrophs need to grow in a histidine/tryptophan-sufficient environment, trace amounts of these amino acids are supplied at the beginning of the test. For each strain of bacteria, variability in the number of revertants can be a result of the number of bacterial cells that are plated at the beginning of the test, the amount of histidine/tryptophan provided initially, the concentration of the test article, the contents of the minimal agar, the amount of S9 mix, the duration of the incubation time, or other factors. In a laboratory, attempts are made to control all factors so that changes in the revertant counts would reflect only the effect of the test article through the concentration levels.

To demonstrate that a compound is not mutagenic, one has to test it at sufficiently high concentrations to rule out doubts that the bacterial cells may not have been challenged enough. Pilot studies are usually conducted first to select proper concentration levels for each strain of bacteria. The final selection often includes concentration levels that are very close to the toxicity threshold of the bacterial cells. Consequently, one may observe a decrease in the number of revertants when some of the concentration levels of a compound are higher than the toxicity threshold of the bacterial cells.

Because the number of bacterial cells plated initially is large (about 10^7) and the probability of a cell undergoing a reverse mutation from auxotrophy to prototrophy is small, the resulting revertant counts of such rare events may have a Poisson distribution. Does the number of revertants X follow a Poisson distribution $p(X = x, \lambda)$ where

$$p(X = x, \lambda) = \frac{\lambda^x e^{-\lambda}}{x!} \quad \text{for } x = 0, 1, 2, \dots \quad (1)$$

and λ is the mean rate of reverse mutation? One can examine this either graphically or by performing a statistical test. To get a good assessment of the distribution assumption, both approaches require more data than are available from one assay in general. When a sufficient amount of data is available, one can check this Poisson assumption by plotting the sample variance against the sample mean on a logarithmic scale. A linear relationship with slope near one is an indication of a Poisson distribution. Or one can perform Fisher's dispersion test^[13] for a sample of n counts, $x_1, x_2, \dots, x_n$, which compares the test statistic

$$\frac{\sum_{i=1}^n (x_i - \bar{x})^2}{\bar{x}} \quad (2)$$

to a chi-square distribution with $n - 1$ degrees of freedom, where $\bar{x}$ is the average of the n revertant counts. Stead et al.^[14] reported no overdispersion in their experience, whereas Vollmar^[15] and Margolin et al.^[16] observed overdispersion. Because each laboratory may have its unique features in conducting the assay and controlling the assay environment, an assessment of overdispersion should be performed based on its own historical data, and reevaluation should be performed periodically.

If the rate of reverse mutation λ from replicate to replicate is not a constant, then the excess of variability in replicates over the mean would suggest that the revertant counts are a random sample from a mixture of Poisson distributions. For ease of further references in later sections, we will follow the parameterization of Margolin et al.^[16] If λ is a random variable with a gamma distribution, then the revertant counts have a negative binomial distribution

$$p(X = x | \mu, c) = (x + c^{-1} - 1) \left(\frac{\mu}{\mu + c^{-1}} \right)^x \times \left(\frac{c^{-1}}{\mu + c^{-1}} \right)^{c^{-1}} \quad (3)$$

for $x = 0, 1, 2, \dots$

where $c \geq 0$ and $\mu > 0$. The mean of this distribution is μ , and the variance is $\mu(1 + c\mu)$. The extra variability in the Poisson counts is reflected by the dispersion parameter c . Large values of c indicate inadequacy of modeling without accounting for the extra variability in the sampling.

MODIFIED TWO- AND THREEFOLD RULES

The two- and threefold rules declare a given test article to have induced a positive response if a concentration-related increase in the number of revertant colonies is at least twice the control count for strains TA98, TA100, and WP2uvrA or three times the control count for strains TA1535 and TA1537.^[17] The comparison is based on the average number of revertants from the replicates for the control and each concentration level. The treated averages are compared to the control average. In the event that there is a decrease in the number of revertants owing to toxicity, the evaluation criteria are applied only to the results at the non-toxic level.

NON-PARAMETRIC METHODS

Vollmar^[15] has examined the results from the European Collaborative Ames-Test Study 1977–1978, and the plots

of log-range versus log-mean indicated that the number of revertants did not follow a Poisson distribution. Overdispersion was evident between laboratories as well as within each laboratory. It was recommended that non-parametric methods be applied to Ames test results. Two rank-based tests were considered: the Jonckheere test^[18] for monotonic concentration effects and the Kruskal-Wallis test^[19] for other effects, including a downturn at the toxic levels. Given 713 Ames test results, the Jonckheere test was superior to the Kruskal-Wallis test and was recommended as the routine statistical method for qualitative evaluations. Vollmar pointed out that, in general, three to five replicate samples were necessary for achieving a statistical significance level of 0.05.

Wahrendorf et al.^[20] have proposed a non-parametric approach to the analysis of Ames test data. Assume that there are K concentration levels with n_k replicates at the k th level and the total number of replicates is N . In their approach, the concentration levels were arranged in K increasing levels, with $K = 1$ for the control. For a given j , $1 \leq j \leq K$, the revertant counts from all K concentration levels are assigned to one of the two categories: 1 is the “below” category for levels 1 to j ; 2 is the “above” category for levels $j + 1$ to K . The revertant counts are ranked from low to high. If there are no concentration-related effects, then the sum of the ranks, L_j , from the “below” category should be the product of the midrank, $(N + 1)/2$, and the number of observations in the “below” category. Define L as the sum of the “below” categories corresponding to j for $1 \leq j \leq K - 1$. If a compound does induce a positive trend in the number of revertants, then the ranks in the “above” category would be relatively higher than those in the “below” category. Therefore, positive trends are associated with smaller values of L , and a test statistic for positive trends is L . Wahrendorf et al. have provided critical values for L based on Monte Carlo simulations for standard designs in their paper. Incorporating the expectation, $E_0(L)$, and variance, $\text{Var}_0(L)$, of L under the null hypothesis of no concentration-related effects, the resulting standardized test T for the alternative hypothesis of an increasing trend is a one-sided test:

$$T = \frac{E_0(L) - L}{\sqrt{\text{Var}_0(L)}} \quad (4)$$

where $E_0(L)$ and $\text{Var}_0(L)$ are defined^[20] by the total sample N and s_j , the number of observations in the “below” category for a given j as follows:

$$E_0(L) = \frac{N+1}{2} \sum_{j=1}^{K-1} s_j \quad (5)$$

$$\text{Var}_0(L) = \frac{N+1}{2} \left[\sum_{j=1}^{K-1} s_j (N - s_j) + 2 \sum_{j=1}^{K-2} \sum_{k=j+1}^{K-1} s_j (N - s_k) \right] \quad (6)$$

The T statistic is approximated by a normal distribution. In addition to the test proposed in the foregoing, Wahrendorf et al. also provided a calculation for the probability $\hat{q}_j$ that a revertant count from the “below” category is smaller than that from the “above” category for a given j . Under the null hypothesis of no concentration-related effects, $\hat{q}_j$ is expected to have a value of 0.5. This probability gives insight to the change of trends in the revertant counts and is helpful for further understanding of the type and strength of the trends.

PARAMETRIC MODELING

Parametric methods include the following: (i) regression on transformed data, assumed to be normally distributed;^[21] (ii) non-linear regression on data assumed to be Poisson distributed, either with or without extra variation, using a full likelihood or quasi-likelihood approach; and (iii) biologically based models incorporating extra-Poisson variation.^[15,22,23]

LINEAR REGRESSION ON LOGARITHMICALLY TRANSFORMED REVERTANT COUNTS

Chu et al.^[21] at the In Vitro Program of the National Cancer Institute (NCI)/National Toxicology Program (NTP) evaluated the statistical methods for Ames test data based on results from 2,362 tests performed in four laboratories on 17 test articles. In defining the screening criteria for adequate data, they defined “toxic dose level” as “any dose level which was greater than the dose eliciting the highest average response and which had every response less than the lowest single response in the highest average response dose level.” Evidence of toxicity is a decrease in the number of revertants after reaching the toxic level. Therefore, when a downturn is present in the revertant counts and the peak mean revertant count occurs at concentration level c_i , then the toxic levels are those concentration levels, c_j , for $j > i$, that have all revertant counts smaller than the lowest revertant count at concentration level c_i .

Once the toxic concentration levels are identified, evaluation of the mutagenic effects will be based on data obtained in the non-toxic concentration range. One approach to the statistical evaluation of the mutagenic effects is regressing the logarithmically transformed revertant count on the logarithmically transformed concentration level.^[21] Because the control concentration level is 0 and the log transformation of 0 does not exist, the recommendation was to increase all concentration levels by 1. The validity of this regression approach lies in the appropriateness of the normality assumption resulting from the log transformation on the revertant counts. Mutagenicity is established by a statistically significant positive slope of the regression line. Chu et al.

required a test to have at least five concentration levels, including a negative control, and each with a minimum of two replicates. When concentration levels are approximately equally spaced, instead of adding 1 to all concentration levels to allow for the log transformation on the 0 concentration level, an alternative was recommended by Margolin et al.^[24] The concentration level of the negative control is selected so that all concentration levels are equally spaced on the logarithmic scale.

NON-LINEAR REGRESSION ON REVERTANT COUNTS

Although rare events are often modeled by Poisson models, and it seems reasonable to consider the small number of revertants in about 10 million bacterial cells a Poisson random variable, there are statistical concerns in the assumption of simple Poisson distribution. Evidence of extra-Poisson variation was observed by some, but not all. Because replicates are required at each concentration level, accumulating historical control data for examination of the adequacy of the Poisson assumption is essential. Under the Poisson assumption, the revertant counts can be modeled by a generalized linear model^[25] with a Poisson distribution and logarithmic link. Positive trends in the treated groups can be tested in a sequential fashion by a trend test^[26] if identifying the concentration level associated with no observable effect is of interest. For laboratories that exhibit extra-Poisson variation in the historical control data, the generalized linear model can be adjusted using a quasi-likelihood method for the extra-Poisson variation. The extra-Poisson variation is accounted for by including an extra factor in the variance of the model. The extra factor can be estimated by the square root of Pearson's chi-square divided by the degrees of freedom. This analysis can be carried out using PROC GENMOD in SAS.^[27]

If the mean rate for reverse mutation, λ , in Eq. 1 is a random variable with gamma distribution, then the posterior distribution of the revertant counts is a negative binomial distribution as in Eq. 3. Thus, the extra-Poisson variation can be incorporated in the modeling and evaluation of the mutagenicity of a compound using a full likelihood approach.

BIOLOGICALLY BASED MODELS

Non-monotonicity observed as a decrease in the revertant counts is not uncommon in practice. Bacterial cells subject to toxicity are inhibited from full expression of mutagenicity. Once a definition of a toxic concentration level is established, then one can eliminate the toxic concentration levels and model the mutagenic effects of a compound using the remaining data. An alternative to this two-step modeling approach is to model both mutagenicity and toxicity of a

compound simultaneously. Margolin et al.^[16] have developed biologically based models for modeling the mutagenicity and toxicity while accounting for the extra variation in the Poisson distribution in the revertant counts from the Ames test. The choice of their models depends on the number of generations the bacterial cells have for their histidine/tryptophan supply, the number of generations the compound is mutagenic, and the number of generations the compound is toxic. Two basic assumptions of the biologically based models are that mutagenic and toxic effects are independent, and durations of bacterial cells, being mutagenic and toxic, are not affected by the concentration of the compound. The mean, μ , of the negative binomial distribution, is related to the number of bacterial cells exposed to the test article, N_0 , and the probability of resulting a revertant colony when exposed to the compound at concentration level d , $P(d)$, as

$$\mu = N_0 P(d) \quad (7)$$

We will discuss the two simplest cases, when the bacterial cells have enough histidine/tryptophan supply for just one generation and the compound is mutagenic for one generation. The first case is when the compound is toxic for one generation. The second case is when it is toxic for infinitely many generations. If a compound is toxic only for one generation, then $P(d)$ is

$$P(d) = (1 - e^{-(\alpha + \beta d)})e^{-\gamma d} \quad (8)$$

where α and β are positive and γ is non-negative. However, if it has long-lasting toxicity, then $P(d)$ is

$$P(d) = (1 - e^{-(\alpha + \beta d)})[2 - e^{-\gamma d}]_+ \quad (9)$$

where $[y]_+ = \max(y, 0)$. The spontaneous reverse mutation rate, mutagenicity, and toxicity are modeled through parameters α , β , and γ . The evaluation of the Ames data is based on Models 8 and 9 in combination with 7 and the negative binomial distribution in Eq. 3 through parameters α , β , γ , and c . If there is no toxicity, then $\gamma = 0$ and Models 8 and 9 are identical. Mutagenicity of a compound is evaluated by testing the null hypothesis of $H_0: \beta = 0$ against the alternative of $H_a: \beta > 0$. Margolin et al.^[16] have approximated the distribution of the ratio of the maximum likelihood estimate of β , $\hat{\beta}$, and its standard error, $SE(\hat{\beta})$, by a standard normal distribution. The $SE(\hat{\beta})$ was obtained based on the Fisher information matrix evaluated at the maximum likelihood estimates of α , β , γ , and c . However, further research by Margolin et al.^[22] has identified problems with the two models. Inflated type I error rates were reported for both models. Their proposal to contain the type I error rates was performing a pretest on $\gamma = 0$ to identify the presence of toxicity. The pretest of $H_0: \gamma = 0$ against $H_a: \gamma > 0$ is a likelihood ratio test:

$$\lambda_\gamma = 2(L(\alpha, \beta, \gamma; c) - L(\alpha, \beta, 0; c)) \quad (10)$$

where $L(\alpha, \beta, \gamma; c)$ is the maximum of the log-likelihood of the data. If the toxicity is not supported by the data, then the mutagenicity parameter β will be tested by the likelihood ratio test in^[10] constrained on $\gamma = 0$:

$$\lambda_\beta = 2(L(\alpha, \beta, 0; c) - L(\alpha, 0, 0; c)) \quad (11)$$

Otherwise, the mutagenicity parameter β will be tested by

$$\lambda_\beta = 2(L(\alpha, \beta, \gamma; c) - L(\epsilon, 0, \gamma; c)) \quad (12)$$

Histidine/tryptophan is necessary for the growth of auxotrophic cells. In the biologically based models described in the foregoing, amino acid diffusion was not considered and each cell will have a local supply of the essential amino acid. However, if the amino acids do diffuse through the plate agar, then the revertant counts should be a function of the amount of histidine/tryptophan as well. Krewski et al.^[23] have proposed generalizing the biologically based models by Margolin et al.^[16] to allow for diffusion of the amino acids in an agar plate.

DISCUSSION

The original and modified two- or threefold rules are simple to use and have been compared to other methods in Refs [21,28]. Chu et al.^[21] have reported favorable performance of the modified twofold rule based on results from 2,362 tests performed in four laboratories on 17 test articles. Definitions of the false positive and false negative are as follows:

- False positive = negative tests determined by consensus of microbiologists that is concluded positive using the decision rule.
- False negative = positive tests determined by consensus of microbiologists that is concluded negative using the decision rule.

Among the methods that gave higher false-positive conclusions than false-negative conclusions are the modified twofold rule, which gave 4.1% false-positive and 1.8% false-negative results, and the positive linear trend test described in the section “Linear Regression on Logarithmically Transformed Revertant Counts,” which gave 20.0% false-positives and 0.4% false-negative results. If the modified twofold rule is supplemented with a modified threefold rule, one would expect the proportion of false positives to decrease further.

For situations where there is no convincing evidence for the assumptions of Poisson distribution, overdispersion in the Poisson distribution, and the normality distribution

of the transformed data, the non-parametric methods discussed in the section “Non-parametric Methods”—namely, the Jonckheere test and the method proposed by Wahrendorf et al.—seem plausible. The latter also provide a descriptive quantity for assessment of the types of increasing trends and the possibility of a downturn due to toxicity. An example of revertant counts of strain TA100 in triplicate of (66, 82, 64), (66, 73, 87), (89, 84, 86), (76, 83, 87), (87, 103, 91), and (89, 98, 82) corresponding to the concentration levels of 0, 10, 30, 50, 100, and 300 μg per plate, respectively, was taken from Stead et al.^[14] The non-parametric method by Wahrendorf concluded a highly significant mutagenic effect with p value = 0.0028 based on normal approximation and p value = 0.0016 based on critical values established by Monte Carlo simulations. If the modified twofold rule were applied to the data, no mutagenic effects would be concluded.

Parametric methods with the assumptions of Poisson distribution with or without extra variation and negative binomial distribution of the revertant counts utilize statistical tools in modeling the counts for mutagenicity, toxicity, and dispersion, whereas the modified twofold rule calls only for simple averages of the revertant counts. Although the modified twofold rule demonstrated good agreement with the consensus of the microbiologists in the NCI/NTP study,^[21] it was considered too conservative by statisticians in general. It is clear that if the statistical methods are adopted, then there will be a great deal of statistically significant findings than using the modified twofold and threefold rules. To address the differences in the mutagenicity of compounds using statistical evaluation and biological evaluation, several issues merit further discussion here:

- i. The use of historical control data.
- ii. The toxicity threshold of a bacterial cell to a test article.
- iii. Extra-Poisson variation in the revertant counts.
- iv. The amount of histidine/tryptophan provided.
- v. The relationship between statistical significance and biological significance.

Clearly, these issues are all interrelated and, therefore, the discussion may not follow the order listed here. Because, in practice, most laboratories conduct Ames tests in triplicate, it is difficult to identify if extra-Poisson variation is present in the revertant counts within each experiment. A historical database for negative control data should be a must for examining the assumption of excessive variation in the revertant counts. In addition, a historical database can provide a base range for the evaluation of compounds that may yield statistical significance that is not biologically important. Because there may be variations among various laboratories, it is best for each laboratory to establish its own database for the historical negative control.

The toxicity threshold of a bacterial cell to a test article may be determined using the rule described by Chu

et al. or by 50–90% lethality. In other words, the number of revertants in the treated plates has to be reasonably low to indicate a toxic effect. Statistical methods can then be applied without modeling the toxic effects. However, if the rules are not accepted by the regulatory agencies, statistical modeling may be the best way to determine the presence of the toxic effects.

Biologically based models for different combinations of mutagenicity and toxicity may lead to different outcomes. How one determines the number of generations that the trace amino acid supply will last, the number of generations the compound will be mutagenic, and the number of generations the compound will be toxic is unclear.

CONCLUSION

At this point, no consensus has been reached on statistical methods for analyzing and interpreting the Ames data. This is reflected both in the existing ICH guidelines for genotoxicity testing,^[5,29,30] and in the revised guideline currently in development,^[31] neither of which mentions any statistical methods for the evaluation of the test results. Considering the small set of numbers that the Ames test provides for each bacterial strain, statistical methods designed to evaluate the mutagenic effects should reflect the biological significance to be of any help to microbiologists. Statistical methods that find biologically small increases to be statistically significant are not desirable and may slow the development of a compound unnecessarily. Any statistical methods recommended for the routine data analysis for the Ames test should be validated by a collection of compounds with known mutagenicity. A historical database is a must in the evaluation of the mutagenicity of compounds and should be established in each laboratory. When a historical database is not available, non-parametric approaches may be a better choice than parametric methods. Statistical methods should support microbiologists' findings when the effects, mutagenic or non-mutagenic, are clear, and should guide scientists when the effects are not clear. Because the modified two- and threefold rules seem to agree well with the consensus of microbiologists,^[21] further work in this area is needed to compare the proposed statistical methods with the modified two- and threefold rules based on known compounds.

Analysis of $2 \times K$ Tables

Shiva Gautam

Harvard Medical School, Boston, Massachusetts, U.S.A.

Abstract

This entry presents some existing methods of analyzing data in $2 \times K$ nominal and ordinal tables, and then discusses some recently developed methods for $2 \times K$ ordinal table as an extension to Pearson chi-square test.

INTRODUCTION

Data in $2 \times K$ contingency tables are encountered quite frequently in biomedical, epidemiological, social, and behavioral studies. The variable representing two rows is often called the row variable, whereas the variable representing K columns is called column variable. (Representation of a data set either in a $2 \times K$ or a $K \times 2$ table is just a matter of convenience.) Depending on the research design, either of the column and row variables may be outcome (response) variables or only one of them may be an outcome variable. More specifically, an observation may have been simultaneously categorized into one of the two rows and into one of the K column categories, or an observation may have been first drawn from a given classification of one of the variables (row or column) and then classified into one of the categories of the other variable (column or row). For example, without taking into account the pros and cons of study designs, consider a possible study to evaluate the association between smoking and lung cancer. The investigator may choose a design in which he/she first selects two groups of people according to whether they have or have no cancer. Then each subject is classified into one of the smoking history categories (e.g., nonsmoker, light smoker, heavy smoker, etc.). Similarly, the investigator may first select people according to smoking status, and then classify each subject from each smoking group according to whether he/she has or has no lung cancer. Finally, the investigator may select a fixed number of subjects and then simultaneously classify them into one of the two lung cancer categories and into one of the several smoking categories. In many situations, the same computational procedures can be used while analyzing data regardless of the study design.

In the analysis of $2 \times K$ nominal table it is important to distinguish between a nominal table and an ordinal table. The data from the lung cancer and smoking study alluded above give rise to an ordinal $2 \times K$ table as the column of the tables (e.g., nonsmoker, light smoker, heavy smoker, etc.) follow an ordering (increasing) or a hierarchy in the

sense that any one category will either be at a higher level or at a lower level than any of the other remaining categories. Sometimes such an ordering among categories is also called simple ordering. A $2 \times K$ table with no ordering, in the sense that any category is neither at a higher nor at a lower level than any one of the other remaining category, is called nominal category. For example, a table showing low-birthweight babies (low birthweight = yes or no) and ethnicity (Asians, Blacks, Hispanics, Whites, etc.) is an example of a $2 \times K$ nominal table.

This paper presents some existing methods of analyzing data in $2 \times K$ nominal and ordinal tables, and then discusses some recently developed methods for $2 \times K$ ordinal table as an extension to Pearson chi-square test.

ANALYSIS OF $2 \times K$ NOMINAL TABLES

Let n_{ij} denote the number of observations in the i th row ($i = 1, 2$) and j th column ($j = 1, 2, \dots, K$) as displayed in Table 1. Also, let $n_{i+} = \sum_{j=1}^K n_{ij}$, $n_{+j} = \sum_{i=1}^2 n_{ij}$, and $n = \sum_{i=1}^2 \sum_{j=1}^K n_{ij} = \sum_{i=1}^2 n_{i+} = \sum_{j=1}^K n_{+j}$. The columns of the table, for the time being, are assumed to be nominal.

Pearson's Chi-Square Test

Perhaps the most popular method for analyzing $2 \times K$ nominal tables is the Pearson's chi-square procedure introduced by Karl Pearson in 1900. The Pearson chi-square test statistic is defined as

$$X^2 = \sum_{i=1}^2 \sum_{j=1}^K (n_{ij} - \hat{\theta}_{ij})^2, \quad (1)$$

where $\hat{\theta}_{ij} = \frac{n_{i+} n_{+j}}{n}$.

The statistic X^2 is asymptotically distributed as the chi-square variate with $(K - 1)$ degrees of freedom. A large value of X^2 provides evidence against the null hypothesis.

Table 1 A $2 \times K$ Contingency Table

Row	Column					Total
	1	2	...	...	K	
1	n_{11}	n_{12}	...	...	n_{1k}	n_{1+}
2	n_{21}	n_{22}	...	...	n_{2k}	n_{2+}
Total	n_{+1}	n_{+2}	...	...	n_{+k}	n

The null hypothesis is often stated as there is no association between the row and column variables. Depending on the research question, the null hypothesis could be that the distribution of proportions in each row (two populations) is the same or the column proportions (K -populations) are the same. As usual, the decision to reject (or not to reject) the null hypothesis is based on the p -value. Agresti^[1] is an excellent source on chi-square analysis of two-way nominal categorical tables.

Likelihood Ratio Chi-Square

Likelihood ratio chi-square statistic is also used to make inference from a nominal contingency table. It is defined as

$$G^2 = -2 \sum_{i=1}^2 \sum_{j=1}^k n_{ij} \log(n_{ij}/\hat{\theta}_{ij}), \quad (2)$$

where $\hat{\theta}_{ij} = \frac{n_{i+} n_{+j}}{n}$.

For large n , G^2 also has chi-square distribution with $(K-1)$ degrees of freedom. Hence both X^2 and G^2 analyses of a given data set in a $2 \times K$ nominal table will generally yield similar results for large n .

Logistic Regression

When the two rows of a $2 \times K$ table represent response, logistic regression may be used to analyze the data by modeling the probability of response (e.g., present vs. absent). Let p = probability of response in the first row. Define dummy variable $X_2, X_3, \dots, X_k$ such that $X_j = 1$ if the observation is from the j th category ($j = 2, 3, \dots, k$), and $X_j = 0$, otherwise. The logistic regression model can be represented as

$$\text{logit}(p) = \hat{\beta}_1 + \hat{\beta}_2 X_2 + \dots + \hat{\beta}_k X_k \quad (3)$$

where $\text{logit}(p) = \log\left(\frac{p}{1-p}\right)$.

Note that $\hat{\beta}_1$ is log odds of responding in row 1 from column 1 (reference column) or equivalently when $X_2, X_3, \dots, X_k$ equal to 0 and X_1 equals to 1. In other words, $\hat{\beta}_1 = \log(n_{11}/n_{21})$. From the above equation $\hat{\beta}_j$ is the excess of log odds responding in row 1 due to the j th column

than the response due to the first column. In other words, $\exp(\hat{\beta}_j)$ represents odds ratio (odds of response due to the j th column compared to odds of response due to the first column).

[Note: Suppose π_1 denotes the probability of lung cancer for smoker, and π_2 denotes the chance of lung cancer for a nonsmoker, then the odds in favor of lung cancer for a smoker is given by $\pi_1/(1-\pi_1)$, and the odds in favor of lung cancer for a nonsmoker by $\pi_2/(1-\pi_2)$. The ratio $\pi_1(1-\pi_2)/\pi_2(1-\pi_1)$ is referred to as the odds ratio which is often used as a direct/indirect measure of the relative risk of a disease (cancer) with an exposure (smoking) relative to the same disease without the exposure. Sample odds ratios are calculated using the observed proportions instead of probabilities.]

One of the advantages of using logistic regression is that it quantifies the magnitude of association. Furthermore, the effect of any additional variables can be adjusted in the model. For example, while evaluating the association of low birthweight (yes, no) and race (Blacks, Hispanics, Whites, Others), investigators may want to adjust for the effect of a covariate (e.g., weight of mothers). Because of these and some other desirable properties and ease of interpretation of coefficients, the logistic regression procedure^[2,3] is widely used to model binary response data from biomedical and other studies.

Maximal Correlation and Pearson's Chi-Square

Consider Table 1 as a sample from a bivariate distribution U (row) and V (column) variable. Let $U = 1$ if an observation is classified into the first row, $U = 0$ if an observation is classified into the second row. Let $V = s_j$ if an observation is classified into the j th category ($j = 1, 2, \dots, k$), where s_j is a real number. The value s_j taken by the variable V corresponding to the j th column of Table 1 will be referred to as a "score" hereafter. Let $r^2\{s_1, s_2, \dots, s_k\}$ denote the square of the Pearson's correlation between U and V for a given set of scores $\{s_1, s_2, \dots, s_k\}$. Let $r_{\max}^2$ denote the maximum of $r^2\{s_1, s_2, \dots, s_k\}$ over all possible sets of scores. Then it can be shown^[4,5] that,

$$nr_{\max}^2 = X^2 \quad (4)$$

where X^2 is the Pearson's chi-square statistics.

It can be shown that the maximal score for $r_{\max}^2$ is given by the set of scores $\{n_{11}/n_{+1}, n_{12}/n_{+2}, \dots, n_{1k}/n_{+k}\}$ or any set of scores obtained from a linear transformation of these scores.^[5] If $r_{\max} = \sqrt{r_{\max}^2}$, then it can be shown that $r_{\max}^2 = (r_{\max})^2 = (r_{\min})^2$, where $r_{\min} = -r_{\max}$. Thus $r_{\max}$ is the maximum possible correlation between the row and column variable, and is always nonnegative.

As mentioned earlier X^2 is simply a significance test and does not provide information on the magnitude of association between row and column variables. As evident from

Eq. 4, a large value of chi-square may result if there is a large sample size even when the association is poor. However, the maximum possible correlation $r_{\max} = \sqrt{\frac{X^2}{n}}$ can be used as a measure of association as it meets several criteria outlined by Goodman and Kruskal for a measure of association.^[6] As $\sqrt{\frac{X^2}{n}}$ is also equal to Cramer's V and the ϕ coefficient, the maximal correlation gives a new meaning to these quantities which are incorporated into the output of some statistical packages. Note that $0 \leq r_{\max} \leq 1$ and $r_{\max} = 1$ if and only if total observations in each column are contributed by only one of the two rows.^[5]

Regression and Pearson's Chi-Square

Consider U and V as row and column variables of Table 1. Furthermore, define $K - 1$ dummy variables $X_2, X_3, \dots, X_k$ corresponding to the second, third, ..., and k th category, respectively (these are the same variables defined earlier in the context of logistic regression). Consider the following predicted line from the linear regression U on $X_2, X_3, \dots, X_k$

$$\hat{U} = \hat{\alpha}_1 + \hat{\alpha}_2 X_2 + \hat{\alpha}_3 X_3 + \dots + \hat{\alpha}_k X_k \quad (5)$$

If R denotes the multiple correlation coefficient then it can be shown that,^[5]

$$nR^2 = X^2 \quad (6)$$

It follows from Eqs. 4 and 6 that $r_{\max}^2 = R^2$. It may be desirable to collapse the columns of a $2 \times K$ table without losing much information.^[7] Gautam and Kimeldorf showed that two columns of a $2 \times K$ table can be collapsed into one if the regression coefficients are equal.^[5] Similarly, if a regression coefficient equals zero then the corresponding column can be collapsed to the column representing the intercept. Therefore, one can test the hypothesis that only a given subset of categories is responsible for the association between the variables. A post hoc analysis may also be performed to find out the reduced table obtained by collapsing categories. This is analogous to testing of the hypothesis

for a subset of regression parameters in multiple linear regression setting.

Exact Tests

Inferences drawn from the above-described analyses of $2 \times K$ tables are based on a large sample theory. When the entries n_{ij} of Table 1 are small then the p -value is obtained directly. For example, exact tests such as Fisher's exact test for 2×2 tables can be extended to a $2 \times K$ table. An exact test for a $2 \times K$ table is often performed by generating all possible tables or randomly generating some large number of tables (e.g., 10,000 tables) with the same marginal totals as the observed table assuming the null hypothesis is true. The p -value is the proportion of tables yielding values of a statistic (e.g., X^2) that are equal to or larger than the value of the same statistic obtained from the observed table.

An Example

Consider Table 2 from Helmes and Fekken.^[8] The table is also reproduced in Agresti.^[1] The table classifies psychiatric patients by their diagnosis and whether the treatment prescribed drugs.

The Pearson chi-square statistic from Table 2 is $X^2 = 84.180$ ($p < 0.0001$, $df = 4$). This suggests an association between the diagnosis and whether or not a patient's treatment prescribed drugs. The above table shows that a schizophrenic patient is most likely to be treated by drugs followed by patient diagnosed as active disorder and personality disorder, respectively. A patient with neurosis has an almost 50% chance of being prescribed drugs, whereas a patient classified as having special symptoms is not likely to be treated by a drug. The Pearson chi-square test rejects the hypothesis that these proportions in the population are the same. In other words, there seems to be an association between the diagnosis and whether or not the treatment prescribed a drug. The last row shows the odds ratio of being prescribed with a drug for a given diagnosis compared to odds of being prescribed with a drug if a patient is diagnosed as schizophrenic.

Table 2 Diagnosis of Patients and Whether Their Treatment Prescribed Drugs

Treatment	Diagnosis					Total
	Schizophrenia	Active disorder	Neurosis	Personality disorder	Special symptoms	
Drugs	105	12	18	47	0	182
No drugs	8	2	19	52	13	94
Total	113	14	37	69	13	276
% Drugs	92.92	85.71	48.65	68.12	0	
Odds ratio	1.0	0.46	0.07	0.07	0	

Source: Ref. [8].

Logistic Regression

Let

$$\begin{aligned} X_2 &= \begin{cases} 1, & \text{if Active Disorder} \\ 0, & \text{otherwise} \end{cases} \\ X_3 &= \begin{cases} 1, & \text{if Neurosis} \\ 0, & \text{otherwise} \end{cases} \\ X_4 &= \begin{cases} 1, & \text{if Personality Disorder} \\ 0, & \text{otherwise} \end{cases} \\ X_5 &= \begin{cases} 1, & \text{if Other Symptoms} \\ 0, & \text{otherwise} \end{cases} \end{aligned}$$

Table 3 shows the results from the logistic regression model presented in Eq. 3.

A quick inspection of Table 3 reveals that the entries in the last column are odds ratios given in the last row of Table 2 except for the entry corresponding to “constant.” The entry corresponding to constant is simply the odds of being prescribed drug in the schizophrenia category ($105/8 = 13.215$). Logistic regression analysis shows that at least one odds ratio is different from one, thus indicating an association between row and column variable. Some caution must be taken while analyzing data in tables with zero entries. A small number is often added to such entries. As an alternate, exact logistic regression analysis can be performed.

A large value of chi-square is indicative of an association between treatment prescribing drug and diagnosis, but it does not indicate whether the statistical significance is a reflection of a strong association or an artifact of weaker association and a large sample size. As discussed above, the maximal correlation could shed further light into this association. From the relationship between the Pearson chi-

square and $r_{\max}$, we have $r_{\max} = \sqrt{\frac{X^2}{n}} = \sqrt{\frac{84.180}{276}} = 0.5523$.

This shows that the observed significant association is not solely due to a large sample size. A natural question that may arise is whether some of the categories can be combined without losing much information.^[7] An investigator may be further interested to determine whether this

association is mostly due to only a few selected categories of the table. Gautam and Kimeldorf^[5] used multiple regression procedure to compute the contribution of a category to the total association noting that $r_{\max}$ is equal to the multiple correlation coefficient R obtained from the regression of row variable U ($U = 1$ if first row and $U = 0$ if second row) on dummy variables X_2, X_3, X_4 , and X_5 defined earlier. They showed that if the 2×3 table is obtained by collapsing columns 1 and 2 together, columns 3 and 4 collapsing together and leaving column 5 the way it is, then the maximal correlation (Pearson chi-square) from this reduced table is 0.5511 (chi-square = 83.824) which is about 99.8% of the maximal correlation (chi-square) from the original 2×5 table.

If the table is reduced to the 2×2 table by collapsing the last four columns into one column, then the maximal correlation from this 2×2 table is 0.4740 (chi-square = 62.011). The reduction in the correlation is 0.0783, and the corresponding reduction in chi-square is 22.179 (p -value < 0.001). Furthermore, Gautam and Kimeldorf argue that this significance is due to the sample size rather than an indication of the weakening of the association due to collapsing of the categories.^[5] The two columns of this table classify patients into schizophrenia and nonschizophrenia groups, and the 2×2 table still retains about 86% of the information provided by the original 2×5 table. Hence the association between row and column variables in the original table is basically the association between diagnosis of schizophrenia (yes or no) and whether the treatment prescribed (yes or no) a drug. In terms of odds ratios, the odds of being on prescription drugs for a person diagnosed with schizophrenia are 14.66 times the odds of being on prescription drugs for a person diagnosed with a nonschizophrenia (95% CI : 6.71–32.04) category.

ANALYSIS OF $2 \times K$ ORDERED TABLES

Pearson's chi-square procedures and other tests developed for analyzing data in $2 \times K$ nominal tables do not incorporate the information on ordering among the columns of the table. These tests are not directed toward any specific alternate hypothesis. In analyzing data in a $2 \times K$ ordered table, investigators will obviously want to use as much information as possible provided by the data and also often want to determine whether the null hypothesis can be rejected against a specific alternate hypothesis (e.g., increasing response with the columns). A test that utilizes ordering information will have increased power compared to a test for nominal tables.^[1]

Methods for analyzing data in $2 \times K$ ordered tables may be broadly classified into two groups, namely, methods that assign and that do not assign numerical scores to the ordered categories, respectively. Methods that do assign numerical scores to the ordered categories may further be

Table 3 Results from Logistic Regression on Data in Table 2

Variable	β	SE(β)	p -value	Exp(β)
X_2	− 0.783	0.847	0.356	0.457
X_3	− 2.629	0.493	0.000	0.072
X_4	− 2.676	0.418	0.000	0.069
X_5	− 23.777	11,147.524	0.998	0.000
Constant	2.575	0.367	0.00	13.125

divided into two subgroups. In the first subgroup of methods, scores are chosen a priori and the analysis is carried out using these scores, whereas in the second subgroup, scores are extracted from the data and thus are functions of the observed data.

Methods Without Scores

One of the widely used methods for analyzing data in $2 \times K$ ordered tables with the two rows representing two populations is the Mann–Whitney or equivalently Wilcoxon rank sum procedure.^[9] Dykstra et al.^[10] proposed a likelihood ratio statistic for testing whether one population with ordered outcome is larger than the other in the sense likelihood ratio ordering. The Likelihood Proportional Odds Model is another method used to analyze $2 \times K$ ordered data without assigning scores to ordinal categories.^[11]

Methods with Scores

Several methods of data analysis for $2 \times K$ ordered tables assign order-preserving scores. The Cochran–Armitage–Mantel trend test is widely used to evaluate the trend in proportion.^[12–14] This trend test requires assignment of order-preserving scores. Another widely used method that utilizes order-preserving scores is logistic regression. The scores are chosen a priori by the investigator, and often, equally spaced scores (e.g., 1, 2, 3, ..., k) are assigned to the ordered categories. In some situations, the ordered categories are defined by actual intervals or actual quantity (e.g., dose level) in which case the scores may be chosen as mid values of the interval or the numerical numbers used to define the categories. The trend test is simply a test of significance and does not provide the magnitude of the association. The slope from the logistic regression is a function of the odds ratio [$\exp(\text{slope}) = \text{odds ratio}$].^[2,3] It is worth noting that the test statistic for the trend test and logistic regression are equivalent for a given set of scores. Hence the p -value from the trend test under the null hypothesis of no trend and the p -value for the logistic regression under the null hypothesis unit odds ratio are the same. When the two rows represent two independent samples, one can compare the row means with a given set of scores using Student's t -test. Again, the p -value from the t -test will also be equal to the p -value from the trend test or the logistic regression if one were to use these methods. Finally, the test of zero correlation (Pearson) between row and column variables would also have yielded the same p -value.

Let the row variable be denoted by U and column variable V with its values as category scores. If $r = \text{corr}(U, V)$ is the correlation between U and V for a given set of order-preserving scores, then the test statistic for the trend test and logistic regression is equal to nr^2 , and the test statistic for the t -test is $t = \frac{nr}{\sqrt{1-r^2}}$ (where n is the number of observations). Therefore, if linear regression instead of

logistic regression is used, then one would obtain the same value of the test statistic and the same p -value while testing the null hypothesis of zero slope. Although the research questions being asked and the design generating a $2 \times K$ ordered table may be different, a common computational procedure may be employed to obtain the statistical significance. Graubard and Korn listed several equivalent test statistics for a given set of scores.^[15]

Choice of Scores

As discussed, several methods (e.g., trend test) of analyzing data in $2 \times K$ ordered tables use order-preserving scores. Even the Mann–Whitney (or Wilcoxon rank sum) test which apparently is a non-score-based method is equivalent to a score-based method. The t -test with mid-rank as category scores is equivalent to the Wilcoxon rank sum test. Cochran noted that any set of scores gives a valid test.^[12] However, different sets of scores may yield different results.^[15]

Iso-Chi-Square Test

Gautam et al. proposed the Iso-chi-square test which is an extension of Pearson's chi-square test.^[16] This test also addresses the issue of arbitrariness of the scores assigned to the columns of $2 \times K$ ordered tables. It was shown earlier that the Pearson chi-square test statistic is equal to $nr_{\max}^2$ where the maximum was taken over all possible column scores (with no restriction on the scores). The Iso-chi-square statistic is given by the same expression but the maximum is taken over all possible order-preserving scores. There is a closed form of solution for the maximal scores and it is given by isotonic regression. However, it is not necessary to extract the maximal scores. The Iso-chi-square is equal to the Pearson chi-square obtained from either the original $2 \times K$ table or from a reduced table obtained by collapsing certain adjacent categories. The null distribution of the Iso-chi-square therefore is given by a mixture of chi-square distributions with 1 to $K - 1$ degrees of freedom. Exact p -values can be obtained by generating tables with given marginal totals. Gautam et al. listed 5% and 1% cut-off values for several values of K .^[16]

Iso-chi-square also addresses the issue of arbitrary assignment of scores to the ordered categories as it reports the maximal value of the test statistics. In cases where there is no clear indication of what scores are to be used, Agresti^[1] suggests using sensitivity analysis by choosing a few sets of scores. Iso-chi-square actually assigns all possible sets of order-preserving scores. It is obvious that Iso-chi-square is also related to the maximal t -statistic and the maximal trend statistic. Iso-chi-square which utilizes all possible scores is equivalent to a method that does not utilize order-preserving scores proposed by Dykstra et al.^[10] and thus links traditional statistical methods with

Table 4 Maternal Alcohol Consumption and Congenital Sex Organ Malformation of the Children

Malformation	Alcohol consumption (average number of drinks per day)				
	0	< 1	1–2	3–5	≥ 6
Absent	17,066	14,464	788	126	37
Present	48	38	5	1	1

the correspondence analysis or dual scaling.^[17] It was also pointed out in an earlier section that the Pearson chi-square test statistic is equivalent to the maximal correlation obtained without order restriction on the scores.

An Example

Consider Table 4, which classifies maternal drinking and congenital sex organ malformation of babies.^[15]

If the two sample Wilcoxon rank sum test is used then the p -value = 0.56 which is also the p -value from the trend test with midranks as category scores. If equally spaced scores {1, 2, 3, 4, 5} are used then the p -value = 0.20 (from the trend test, t -test, logistic regression, linear regression, and correlation analysis). In an example such as this perhaps the mid-values of the interval represent the underlying continuous measure. Graubard and Korn used scores of 0, 1.5, 4.0, and 7 (somewhat arbitrary) which yield a p -value equal to 0.01.^[15] Iso-chi-square analysis for this data set yields a p -value of 0.02. These are exact p -values.

Stochastic Ordering

Stochastic ordering, in the context of a $2 \times K$ ordered table, is defined as having the cumulative distribution function (CDF) of one of the rows not crossing the distribution function of the other. In terms of the entries of Table 1, $F_{1j} = \sum_{i=1}^j n_{1i}/n_{1+}$ and $F_{2j} = \sum_{i=1}^j n_{2i}/n_{2+}$. If $F_{2j} \leq F_{1j}$ for all $j = 1, 2, \dots, K$, then row 2 is stochastically larger than row 1 (in the observed sample data). It is interesting to note that row 2 is stochastically larger than row 1 if and only if all order-preserving scores yield a larger (or equal) mean for row 2 than the corresponding mean for row 1. Kimeldorf et al. computed the minimum and maximum t -statistics, and argued that if the minimum t -statistic is positive and significant (or the maximum t -statistic is negative and significant), then any set of order-preserving scores will produce a significant result.^[18] This could be used as an evidence of stochastic ordering in a given $2 \times K$ table. Berger et al. propose the convex hull test for ordered categorical data.^[19]

CONCLUSION

In this article some existing methods of analyzing data in $2 \times K$ ($K > 2$) contingency tables are discussed. Pearson's

chi-square test statistic which is widely used to analyze nominal data is shown to be related to maximal correlation. Using maximal correlation an investigator may determine if only a few categories contribute to the observed association. This relationship between the chi-square and the maximal correlation may also shed light on whether the large value of the chi-square test statistic is only due to a large sample size.

The paper also discusses methods of analysis of $2 \times K$ ordered table. Some of these methods use order-preserving scores and others that do not use such scores. Several of the methods that utilize scores are equivalent to each other. As these methods are directed toward a particular alternative hypothesis they have more power in general than the methods that do not utilize such scores. Also, these methods are computationally simple. However, the scores chosen are often arbitrary. In many situations the columns may provide some indication (e.g., interval, actual dose of a drug, etc.), where it makes sense to use certain scores. But in a situation where the columns are defined as "low," "medium," and "high," it may be difficult to come up with a set of score. In such situations, the Iso-chi-square method may be useful. Iso-chi-square may be considered as a natural extension of the Pearson chi-square to the $2 \times K$ ordered table in the sense that if this procedure is applied to $2 \times K$ nominal tables, the test statistic is the Pearson's chi-square test statistic. Also, Iso-chi-square may be considered as a link between methods that do and do not utilize order-preserving score.

All the $2 \times K$ tables discussed here are assumed to have simple ordering. There may be other types of tables where the ordering between two categories is not simple. For example, parental drinking or smoking may be classified as "neither parent," "mother only," "father only," and "both parents." The level of the first or the last category has a distinct hierarchy compared with any other categories. However, such a hierarchy between the second, the first, and the third is not defined. Similarly, some $2 \times K$ tables may have mixed categories (both nominal and ordinal categories) or may have open-ended categories.^[20,21] The method of Iso-chi-square may be extended in such situations. Gautam presented a case where the choice of an open-ended category may influence the statistical conclusion in the context of the trend test and argued that such an analysis may be misleading.^[22]

Analysis of Clustered Binary Data

Valerie Durkalski

Division of Biostatistics and Epidemiology, Medical University of South Carolina, Charleston, South Carolina, U.S.A.

Abstract

When a subject contributes more than one binary response (paired or unpaired), it results in clustered data in which the subject is the cluster and each response within a cluster is a unit. The focus of this entry is on various methods of analysis in terms of clustered binary data. Specifically, this entry deals with the ICC, pooled estimators, method of moments estimators, and GEE approaches.

Keywords: Binary outcomes; Chi-square test; Clustered data; GEE.

INTRODUCTION

Clinical trial designs often incorporate binary outcomes (i.e., proportion of responders; success probabilities) or change continuous outcomes into binary outcomes for interpretation purposes. When a subject contributes more than one binary response (paired or unpaired), it results in clustered data in which the subject is the cluster and each response within a cluster is a unit. In this scenario, responses are considered dependent within a cluster, and independent between clusters.

One can imagine several distinct contexts in which clustered binary data might arise. Examples include ophthalmology studies, in which the unit is each eye, but more generally the number of units may vary across clusters. This more general formulation then includes dental studies, in which the unit of analysis is each tooth, oncology studies, in which the units are infected nodes or lesions within a patient, and community intervention studies, in which the unit is the individual within the community. When dealing with two treatments, it would be possible for some clusters, and every unit in those clusters, to be assigned to one treatment group, and for the other clusters, and every unit in these other clusters, to be assigned to the other treatment group. For example, to examine the success of two teaching programs on the graduation rate in one school, one may randomize classrooms (cluster) to the treatment and have students be the unit of analysis. Fear of contamination would preclude one from randomizing students within the same classroom to different teaching conditions. This is also the context for repeated measures studies, in which the cluster is the patient and the units are the sampling times. Such a design allows for the separation of effects due to between-subject variability from effects due to within-subject variability.^[1] It is also possible that each cluster receives both treatments, but each unit within

each cluster receives one treatment or the other, such as in some ophthalmology studies, where one eye is given one treatment and the other is given the comparison treatment. A third context would be in which each unit receives both treatments, such as in matched-pair designs, where clusters (i.e., subjects) act as their own control and receive both procedures/interventions, or clusters are matched with each receiving one of the procedures/interventions.

At the unit level, the correlation between units within a cluster violates the independence assumption of many of the statistical methods for analyzing binary outcomes, such as Pearson's chi-square, McNemar's test, and logistic regression. This violation may decrease standard error estimates and the p -value associated with the test statistic, thereby yielding misleading statistical conclusions. The challenge that arises when analyzing clustered binary data, therefore, is handling the correlation among units within a cluster. While cluster summary approaches such as collapsing data within a cluster or focusing the design on cluster-level analyses are valid in some cases, they do not use all available data, and so more informative analysis techniques would be expected to yield more precise results. Unit-level analyses are the focus of this entry.

METHODS OF ANALYSIS

Methods for the analysis of clustered binary data (paired and unpaired) are well developed.^[2,3] Most research directly addresses important theoretical and applied issues regarding the effect of clustering and the consequential effect on the variance and on the statistical conclusions. Adjustments for correlated binary responses within a cluster have been incorporated into statistical tests using a correlated binomial model,^[4] Fisher's permutation test,^[5] binomial ratio estimators,^[6,7] pooled estimators,^[8] method of moments

estimators,^[9] and intracluster correlation (ICC).^[10] Another approach that is widely applied is marginal regression modeling using the general estimating equation (GEE) approach of Zeger and Liang.^[11] Although these comparison methods have been developed for clustered binary data, not all tests are consistent in terms of performance. Depending on the cluster sizes and the correlation structure within clusters, the tests performances may vary in terms of size and power. This entry focuses on the ICC, pooled estimators, method of moments estimators, and GEE approaches.

To review different analysis methods, three subscripts are defined in the case of two proportions, as follows. Let the response variable Y_{ijk} be dichotomous (1 = success, 0 = failure), where i (=1, 2) is the treatment or intervention, j (=1, 2, ..., n_k) is the unit within the cluster, and k (=1, 2, ..., K) is the cluster. Let $\hat{p}_{ik} = n_{ik}^{-1} \sum_{j=1}^{n_k} Y_{ijk}$ be the event rate (i.e., proportion of successes) in group i for cluster k ; K is the total number of clusters in the study population, and $N = \sum_{k=1}^K n_k$ is the total number of units across all the clusters for both treatments. The n_k units in the k th cluster are assumed to be fixed for all K clusters. With this framework, the data from each unit within each cluster can be summarized as a standard 2×2 contingency table, as both treatment and outcome vary, and are binary variables (assuming that there are only two treatments). The frequencies of the responses per group may be summed over all K clusters. This data display is presented in Table 1 for independent bivariate random variables and in Table 2 for dependent bivariate variables (matched-pair data).

HYPOTHESIS TESTING

When dealing with bivariate random variables, one for each of two treatment conditions, it is often of interest to test the hypothesis of equality of the probabilities of a positive response across the treatment conditions. Doing so is fairly straightforward when subjects are allocated to treatment groups by random allocation, with either no restrictions at all on the randomization or with the only restriction being that the group totals are fixed. In either case (conditioning on the random group totals in the first case), the

design-based analysis is Fisher's exact test.^[12] When clustering is present, however, this would not be an appropriate analysis, because it would ignore the clustering.

To avoid underestimating the variance of the parameter in the presence of clustering, Donner and colleagues explore a model using the intracluster correlation coefficient (ICC), which adjusts the chi-square test for correlation within clustered data.^[13,14] The ICC, originally applied to interobserver agreement analyses as an alternative to Cohen's kappa, an index of agreement between two or more raters, is estimated using the mean square errors of analysis of variance (ANOVA) for mixed models, where the treatment is constant and the cluster is random. The estimated ICC represents the proportion of variation due to between-cluster differences. Donner presents a detailed explanation of how a consistent estimate of the ICC is calculated under the assumption of a constant ICC across clusters.^[5] The ICC adjustment is applied to the Pearson chi-square test,^[13] chi-square test for linear trend,^[14] Mantel-Haenszel test,^[15] and McNemar test.^[16] The test statistic is adjusted by dividing it by an inflation factor, $C_i = 1 + (m-1)\hat{\rho}$, where m is the average number of units per cluster for treatment group i and ρ is the estimated ICC for clustering,

$$\hat{\rho} = \frac{\text{BMS} - \text{WMS}}{\text{BMS} + (S_0 - 1)\text{WMS}}$$

In this equation, BMS is the mean squared error between subjects, WMS is the mean squared error within subjects, and S_0 is the adjusted mean cluster size. The ICC approach for adjustment of a chi-square test is an extension of a standard chi-square test, because when $\rho = 0$, the adjusted test reduces to the standard test with one degree of freedom. Therefore, if there is only one unit per cluster, the standard test to compare overall event rates can be adopted,

$$\chi^2 = \sum_{i=1}^2 \frac{n_i(p_i - \hat{p})^2}{C_i \hat{p}(1 - \hat{p})}$$

where $p_i = \sum_{k=1}^K p_{ik}$ and $\hat{p}$ is the overall event rate. In addition, the test can be extended to the comparison of more than two treatment groups.^[14] Although the ICC appears to be quite adaptable to adjusting a variety of chi-square tests, this method has limitations regarding the required size of the study population and the test assumptions. Donald and Donner^[13] suggest that the number of units per cluster should be greater than 10 and the ratio of the number of units to the number of observations per unit should be greater than two when applying the adjusted chi-square to Pearson's chi-square test for homogeneity of proportions. They also note that the method's assumption, that the correlation between responses within a cluster is equal, may not be appropriate when the probability of a correct response varies

Table 1 Contingency Table for Clustered Binary Data

	Response	
	Success	Failure
Group 1	$\sum_{k=1}^K \sum_{j=1}^{n_k} y_{1jk}$	$\sum_{k=1}^K \sum_{j=1}^{n_k} (n_1 - y_{1jk})$
Group 2	$\sum_{k=1}^K \sum_{j=1}^{n_k} y_{2jk}$	$\sum_{k=1}^K \sum_{j=1}^{n_k} (n_2 - y_{2jk})$
	$\sum_{k=1}^K \sum_{j=1}^{n_k} (y_{1jk} + y_{2jk})$	

Table 2 Contingency Table for Clustered Matched-Pair Binary Data

		Procedure 1		
		Success	Failure	
Procedure 2	Success	$\sum_{k=1}^K \sum_{j=1}^{n_k} a_{jk}$	$\sum_{k=1}^K \sum_{j=1}^{n_k} b_{jk}$	$\sum_{k=1}^K \sum_{j=1}^{n_k} (a_{jk} + b_{jk})$
	Failure	$\sum_{k=1}^K \sum_{j=1}^{n_k} c_k$	$\sum_{k=1}^K \sum_{j=1}^{n_k} d_k$	
		$\sum_{k=1}^K \sum_{j=1}^{n_k} (a_{jk} + c_{jk})$		$\sum_{k=1}^K \sum_{j=1}^K n_k = N$

The joint probabilities of success and failure between the two procedures are $p_{11} = N^{-1} \sum_{k=1}^K E[a_k]$, $p_{10} = N^{-1} \sum_{k=1}^K E[b_k]$, $p_{01} = N^{-1} \sum_{k=1}^K E[c_k]$, and

$$p_{00} = N^{-1} \sum_{k=1}^K E[d_k].$$

between units within a cluster or when the correlation is dependent upon the size of the cluster. However, Jung et al.^[17] illustrate through simulation studies that the adjustment method performs well even if the assumption of a common intracluster correlation is not met, as long as the intraclusters are only moderately different. Nonetheless, certain data situations where this assumption may not hold include lesion detection, where the number of lesions per subject can vary widely and the detection of a lesion can depend on several factors, including its size and location.

To avoid the limitation inherent in the aforementioned analysis, other techniques would need to be implemented. For example, Rao and Scott^[6] have developed a method that avoids having to calculate an intracluster correlation and thus avoids the assumption of a constant correlation between units within cluster. Based on a sampling technique, an inflation factor is defined that accounts for clustered observations. This inflation factor is equal to the variance estimate of the ratio of positive responses,

$$\text{var}(\hat{p}_i) = \frac{K_i}{K_i - 1} \left(\frac{\sum_{k=1}^K (y_{ik} - n_{ik} \hat{p}_i)^2}{\left(\sum_{k=1}^K n_{ik} \right)^2} \right)$$

divided by the estimated binomial variance of the proportion of positive responses, $n_i^{-1} \hat{p}_i (1 - \hat{p}_i)$. Rao and Scott refer to the inflation factor as the “design effect” and apply it to the standard chi-square test with $I - 1$ degrees of freedom,

$$\tilde{\chi}^2 = \sum_{i=1}^I \frac{(\tilde{y}_i \tilde{p})^2}{[\tilde{n}_i \tilde{p}(1 - \tilde{p})]}$$

The number of positive responses (y_i), number of units (n_i) and event rate (p) in the chi-square equation are each adjusted by the design effect and applied to the one degree of freedom chi-square statistic. The design effect approach is best utilized when the mean cluster size differs between comparison groups. The limiting factor of this *sampling*

approach is that a relatively large number of clusters is suggested in order to obtain a consistent ratio estimator.

Following a similar approach, Obuchowski^[8] has developed a test for clustered matched-pair data that pools the probability of a success across all clusters and all tests, where p in the above equation is replaced with $\bar{p}$, which is the average of the proportions of success for each procedure: $\bar{p} = (\hat{p}_i + \hat{p}_i') / 2$. The homogeneity hypothesis and the numerator of the test statistic remain the same as in the McNemar test, except that the overall sample proportion of positive units detected by procedure i ($\hat{p}_i$) is estimated by counting the number of positive responses by procedure i summed over all K clusters, e.g., $\sum (a_k + b_k)$ for Procedure 1 and $\sum (a_k + c_k)$ for Procedure 2. The test is asymptotically distributed as a chi-square with one degree of freedom under the null hypothesis,

$$\chi_0^2 = \frac{(\hat{p}_i - p_i')^2}{\text{var}(p_i - p_i') \bar{p}}$$

where

$$\text{var}(\hat{p}_i - \hat{p}_i')_{\bar{p}} = \text{var}(\hat{p}_i)_{\bar{p}} - 2 \text{cov}(\hat{p}_i, \hat{p}_i')_{\bar{p}}.$$

Obuchowski compares this method to the ICC adjustment. Under specific conditions (i.e., a cluster size ≤ 5 , three different correlation structures, and various sample sizes), the proposed method performs similar to the ICC in terms of maintaining a type I error rate below 0.05. The main difference between the two procedures is that the sampling approach does not take into account within-cluster correlation.

An alternative approach proposed by Durkalski and colleagues utilizes a method of moments approach for the analysis of clustered matched-pair data.^[9] The proposed test statistic is

$$\chi_V^2 = \frac{\left[\sum_{k=1}^K (1/n_k)(b_k - c_k) \right]^2}{\sum_{k=1}^K [(b_k - c_k)/n_k]^2}$$

because under the null hypothesis, the estimated variance of the difference in success rates is

$$\text{var}(\hat{p}_{10} - \hat{p}_{01}) = \frac{1}{K^2} \sum_{k=1}^K \left[\frac{(b_k - c_k)}{n_k} \right]^2$$

This estimate of the variance is consistent according to large sample theory. Based on simulations, the method of moments approach performs as well in terms of size and power as the McNemar test adjusted by the ICC and Obuchowski's approach for clustered matched-pair data. Moreover, this method has been extended to account for non-inferiority study designs.^[18]

GENERAL ESTIMATING EQUATIONS

Although adjusting the chi-square test for the equality of probabilities is popular, more complex analyses that incorporate covariate effects may also be of interest. These analyses require sophisticated models that account for the correlation within clusters. A popular method due to the availability of statistical software is the application of generalized linear models.^[19] Based on this model, marginal regression modeling using GEEs was developed as a semiparametric approach to fitting logistic regression models for binary clustered data.^[11] The logistic regression model using the GEE estimating function obtains similar results as the adjusted chi-square tests previously discussed in this entry when covariates are not present. This model is defined as $\log \text{it } \text{pr}(\gamma_{ijk} = 1) = \beta_0 + \beta_1 x_{ijk}$ where x_{ijk} identifies the i th treatment variable from the j th unit of the k th cluster (in the case of two treatments) and can be run using PROC GENMOD in SAS.^[20] The p -value is generated from a comparison of the log odds ratio to the estimated variance. Because clustering affects the standard errors of the parameter estimates rather than the parameter estimates themselves, the parameter estimates can be obtained by running a regression analysis on each response. The logit link expresses the linear relationship between a cluster's responses and the corresponding covariates. The correlation within a cluster is accounted for in the variance-covariance matrix. To estimate the variance of the response, a specified "working" correlation matrix that defines the association among units within a cluster substitutes for the true, often unknown, correlation matrix. Although the working correlation matrix may be misspecified, which could possibly result in a decrease of efficiency, the GEE method can produce consistent estimates.^[11] Furthermore, the decreased efficiency may be minimal if the number of clusters is large.^[21] Prentice^[22] extends Zeger and Liang's model to incorporate the modeling of correlations within a cluster in order to improve upon the efficiency of the GEE estimates of the regression parameters. Although the GEE method is more complex

than the straightforward comparison of event rates, the attractiveness of this approach is that it easily incorporates adjustments for covariates when needed. Methods for binary regression using clustered data deserve an entry of their own and are not discussed further.

EXAMPLE

To illustrate the clinical application of commonly used methods for analyzing clustered binary data and the importance of accounting for the clustered nature of the data, Donner and Klar^[23] consider data collected from schools randomly allocated to one of two interventions. The outcome of interest is the proportion of children who use smokeless tobacco after two years of follow up. The performance of various methods for testing the equality of clustered binary data is observed, including the test statistics and p -values of the unadjusted Pearson chi-square, the ICC inflation factor, the design effect inflation factor, and the GEE approach. The test statistics and p -values illustrate that statistical conclusions can be false when clustering is ignored (using the standard chi-square test), while all methods that adjust for clustering give relatively the same conclusions with some variability in the actual test values and significance levels.

For matched-pair data, a data set containing clustered matched-pair data that appeared in Obuchowski's paper^[8] is assessed with the unadjusted McNemar test, the ICC adjustment, pooled estimators, and the method of moments approach. A trial in diagnostic methods for hyperparathyroidism is designed to compare the sensitivity and specificity of two techniques, positron emission tomography (PET) and a single photon emission CT (SPECT) scan. The data consist of 21 patients whose glands were examined for the presence of hyperparathyroidism (Table 3). Of the 21 patients, a total of 72 glands were evaluated by both diagnostic tools. The specificity of the two scanners is considered to be of interest and, therefore, only the glands that are confirmed negative by surgery (considered the gold standard) are evaluated. Of the 72 glands among the 21 patients, a total of 51 glands were confirmed negative. The estimated intraclass correlation is equal to 0.46. Obuchowski's, Donner's, and Durkalski's test results are chi-square values of 2.86 ($p = 0.091$), 3.66 ($p = 0.056$), and 2.32 ($p = 0.128$), respectively. The unadjusted McNemar test statistic is 4.5 ($p = 0.034$).

All the tests that account for clustering fail to reject the null hypothesis of no difference between the two procedures (at the 0.05 level), whereas the McNemar test (which does not account for the clustering) concludes that a statistically significant difference does exist (at the 0.05 level) in the specificity of PET and SPECT. This is not surprising, because as seen in Donner and Klar's comparisons, accounting for clustering means assigning less weight to multiple observations from the same cluster. Without doing

Table 3 Hyperthyroid Data

K	n_k	y_{ik}	y'_{ik}	a_k	b_k	c_k	d_k

18	3	2	3	2	0	1	0
19	2	2	2	2	0	0	0
20	1	1	1	1	0	0	0
21	2	2	2	2	0	0	0

$$K = 21, N = \sum_{k=1}^K n_k = 51, y_{ik} = \sum_{j=1}^{n_k} y_{ijk} = 40, y'_{ik} = \sum_{j=1}^{n_k} y'_{ijk} = 46,$$

$$a = \sum_{k=1}^K \sum_{j=1}^{n_k} a_{jk} = 39,$$

$$b = \sum_{k=1}^K \sum_{j=1}^{n_k} b_{jk} = 1,$$

$$c = \sum_{k=1}^K \sum_{j=1}^{n_k} c_{jk} = 7,$$

$$d = \sum_{k=1}^K \sum_{j=1}^{n_k} d_{jk} = 4. \text{ (From Ref. [8].)}$$

this, these multiple observations would have more influence than they perhaps should, and this could easily lead to pseudopower, or a false rejection of a true null hypothesis.

CONCLUSIONS

Clustered binary data are prevalent in medical research. Ophthalmology studies, dental research, oncology studies, and community research programs often involve multiple layers, which violate the basic assumption of independence for common statistical methods. Methods for analyzing clustered binary data are available and continue to be developed and enhanced. All methods account for the within-cluster correlation; yet, it is the approach to doing so that makes them different. The appropriate strategy is dependent on the research question being explored and the data structure in terms of cluster size and cluster covariates.

Due to the availability of current statistical software, the majority of methods discussed in this entry are simple to implement in practice. Therefore, the collapsing of the data to a single-level model should be avoided. Ignoring the cluster effect or collapsing of data has been shown throughout the literature to create biased estimates, which can lead to false statistical conclusions (as was the case in our examples). If a simple test of the equality of event rates is being performed and a relatively small difference in mean cluster size between comparison groups is present, then the ICC approach is convenient to implement and can be extended to a number of data scenarios, including stratified or matched-pair data.

For more complex study designs, such as those that incorporate covariates or multiple cluster levels (perhaps classrooms within school districts or designs that have a combination of clustered and longitudinal data), hierarchical modeling approaches are available and continue to be explored.^[1,3] It is worthwhile to mention that during the planning stages of a study that involves clustered binary data, the statistician needs to consider inflating the sample size to offset the loss of information that occurs due to the clustering. Considerations for sample size estimation for clustered binary data are available in the literature.^[24,25]

Analysis of Clustered Categorical Data

Kalyan Das

Department of Statistics, University of Calcutta, Kolkata, India

Abstract

This entry discusses models in the bivariate setup. It also discusses the limitations considering the normality assumption of the subject specific effects and proposes some nonparametric distribution instead.

INTRODUCTION

Social, behavioral, and epidemiological studies are often concerned with multiple discrete indicators that are utilized as responses in lieu of an obvious single measure for an outcome of interest. Sometimes these multiple indicators corresponding to a subject are each rated with natural ordering. For example, in order to study the efficacy of a new drug, patients who received a certain dose of that drug are observed at weekly intervals. Their responses are recorded in terms of multiple indicators and an obvious ordering in terms of patient's improvement may be seen. The ordered responses of the patient (within a cluster) are likely to be positively correlated. Repeated measurements instead of different time points may refer to matched sets. In statewide studies of cancer screening in primary care practices, interest is in the physician and patient factors that predict the extent of breast cancer screening that a woman receives. The outcome for each woman takes a value of 0, 1, or 2 for the number of types of screening procedures (mammogram and clinical breast examination) observed over successive periods in the past year. The statistical analysis should consider that the level of one woman's cancer screening may be correlated to that of another patient in the same medical practice. In a randomized clinical trial on survey for duodenal ulcer, the postoperative pain level (none/slight/moderate/severe) and medication requirements (never/seldom/occasionally/regularly) of each patient are observed together over days. The objective may be to study the association between these two as related to different types of operation for duodenal ulcer (VP—vagotomy and drainage procedure, VA—vagotomy and distal antrectomy, VA—vagotomy and hemigastrectomy, RA—resection alone). The prime concern, therefore, is to find a suitable model to describe the relationship between the paired ordinal responses and the available covariates. In oral hygiene studies, plaque formed on six well-defined teeth of each subject may be measured as per Quigley-Hein index for plaque scoring. The primary objective may be to study the role of factors—such as smoking

habits, food habits, and efficacy of toothbrushes—that predict the extent of formation of plaque. Once again, those six teeth in an individual's mouth are all intradependent. Prior to the advent of increasingly powerful computing, statistical analysis was mostly limited to large sample χ^2 methods based on contingency tables. In recent years, there has been growing interest in exact inference. As a result, estimation and hypothesis testing for tables with small samples can be made efficiently by using exact methods with the help of advanced computing techniques. Although the non-model-based Mantel-Haenszel's method is quite useful when the basic requirements of sample size are met, variations of this method that adjusts for continuous covariates are yet to be studied extensively. This review primarily focuses on the second approach. Due to enormity of the subject, we do not attempt an exhaustive review of the literature but often refer to other books or articles that document many contributions to this field.

In many biological studies, categorical responses are observed from highly stratified random samples with a large number of strata (clusters) each consisting of a few observations. Our primary objective is to analyze data under this kind of setting. Marginal models analyze effects averaged over all clusters at particular levels of predictors. Alternatively, one can proceed through cluster specific (conditional) models using random effects that describe effects at cluster level.

MODELS FOR CLUSTERED CATEGORICAL DATA

Approaches based on logistic regression models were developed four decades ago to describe the relationship between a categorical response variable and a set of explanatory variables that may include both categorical and continuous variables. We emphasize here unconditional logistic regression mainly for its application in life data analysis. Models for ordinal responses have received much attention and since 1960, there have been several proposals (Smell,^[1]

Bock and Jones,^[2] McCullagh,^[3] Goodman.^[4] The proportional odds model^[3] specifies a cumulative logit link to relate p covariates to (a r category) ordinal response with corresponding multinomial probabilities $\pi_1, \dots, \pi_r$ such that $\sum_{j=1}^r \pi_j = 1$. The model is then

$$\text{logit } P(y_t \leq j | x_t) = \alpha_j - x_t' \beta_j, j = 1, \dots, r \quad (1)$$

where y_t denotes an individual's t th response, $t = 1, \dots, T$, which can take one of r possible categories, $j = 1, \dots, r$. x_t consists of the values of the explanatory variables corresponding to the t th observation in a cluster. The parameters $\{\alpha_j\}$ called cut points are usually nuisance parameters whereas the parameters $\{\beta_j\}$ have their usual interpretations.

Proportional Odds Mixed Models

Ordinal outcomes are observed frequently in many field of investigations such as small area surveys, longitudinal studies, disease mapping, and others. Typically in those situations, data observed across time or locations form some sort of clustering and therefore become correlated within themselves. This causes additional variability that needs to be taken into account in order to draw appropriate inference from the data. To do that, it is natural to introduce an unobserved random component in the linear predictor of the model defined in Eq. 1. But a major difficulty in these models is that a full likelihood analysis often involves intractable numerical integration with respect to mixing distribution of random effects. Usually, two classes of models are considered: marginal models or population average models, where effects are averaged over clusters at particular levels of predictors; or subject specific (cluster specific) models, which are conditional models that describe effects at each cluster level. The basic purpose of this review is to highlight the recent methodological developments on subject specific models. Essentially, one can extend the proportional odds model to a subject specific model (see Tutz and Hennevoogt^[5]) as

$$\text{logit } P(y_{it} \leq j | x_{it}, u_i) = \alpha_j - x_{it}' \beta + z_{it}' u_i, \quad (2)$$

$i = 1, \dots, n, t = 1, \dots, T, j = 1, \dots, c$

where $(y_{i1}, y_{i2}, \dots, y_{iT})$ denote T repeated responses in the i th cluster (subject), u_i denotes the subject (cluster) specific random effect with mean 0 and variance Σ . The parameters $\{\alpha_j\}$ called cut points are usually nuisance parameters. Specifically, this model implies that odds ratios for describing effects of explanatory variables as the response variable are same for each possible ways of collapsing a “c” category response to a binary variable (McCullagh^[3]). In the binary set up the model in Eq. 2 reduces to

$$\text{logit } P(y_{it} = 1 | x_{it}, u_i) = x_{it}' \beta + z_{it}' u_i.$$

Latent Mixed Models

A clustered ordinal model can be developed through threshold concept. In such models, conventionally one assumes that there is an unobserved latent variable (y^*) that is related to the actual response though the introduction of a threshold variable. In fact for the ordinal model a series of threshold values $\alpha_1, \dots, \alpha_{J-1}$ where J equals the number of ordered categories $\alpha_0 = -\infty, \alpha_J = \infty$. Here a response occurs in category j ($y_{it} = j$) if the latent response process y^* exceeds the threshold value α_{j-1} but does not exceed the threshold value α_j . Thus for the categorical variable “ y ” obtained by chopping y^* into categories (with cut point $\{\alpha_j\}$) the proportional odds model holds for predictor with effects proportional to those in the continuous model. One can therefore, write the model

$$\begin{aligned} P(y_{it} = j | \beta, \alpha) &= \Phi \left[\left(\frac{\gamma_j - x_{it}' \beta - u_i}{\sigma} \right) \right] - \Phi \left[\left(\frac{\gamma_{j-1} - x_{it}' \beta - u_i}{\sigma} \right) \right] \\ \text{or, } &= \bar{\Psi} \left[\left(\frac{\gamma_j - x_{it}' \beta - u_i}{\sigma} \right) \right] - \bar{\Psi} \left[\left(\frac{\gamma_{j-1} - x_{it}' \beta - u_i}{\sigma} \right) \right] \end{aligned} \quad (3)$$

where $\Phi(\cdot)$ and $\bar{\Psi}(\cdot)$ represent the cumulative standard normal distribution function and the logistic function, respectively. For convenience, we take $\gamma_1 = 0$ and $\sigma = 1$ ($\sigma = \pi^2/3$ for logistic model).

Note that alternatively we can consider a log linear model (Goldstein^[6]) for clustered categorical data that can include multiple random effects but such a model corresponds to an ordinal regression model only when the number of categories is 2 (see McCullagh^[3])

Multilevel Models

Model in Eq. 3 can be viewed as a two-level model where i denotes the level-2 units (cluster in the clustered data context or subjects in the longitudinal data context) and t denotes the level-1 units (subjects in the clustered data context or repeated observations in the longitudinal data context). Thus the random effect regression model for the latent response y_{it}^* is

$$y_{it}^* = x_{it}' \beta + z_{it}' u_i + \varepsilon_{it} \quad (4)$$

where the conjugate vector x_{it} and random effects design vector z_{it} are associated with the t th level-1 unit nested within level-2 unit i and ε_{it} are residuals. Hedeker and Gibbons^[7] and Liu and Hedeker^[8] considered multi-level representation of ordinal response model in a more extended way.

Multivariate Clustered Ordinal Model

Marginal Models

We discuss a multivariate ordinal categorical model accounting for the heterogeneity. This kind of models has received much attention lately. Here emphasis is on the efficient estimation of the effect of covariates on the marginal distribution of ordinal responses. Such a model without any random term has been proposed earlier (Molenberghs and Lessaffre^[9], Dale^[10]). In view of its elegant statistical properties such a model appears to be a good candidate for modeling categorical dependent variables. This model is quite flexible as the marginal and association structures can be modeled easily. Furthermore, here the odds ratio is easier to interpret than a multivariate probit model. The details of the model construction have been addressed in Molenbergh and Lessaffre.^[9] In fact, in particular, for the bivariate model we may consider the following model for subject i as

$$\begin{aligned}\text{logit } P(y_{1it} \leq j_1 | x_{1t}) &= \alpha_{1j_1} - x'_{1it} \beta_1 + z'_{1it} u_{1i} \\ \text{logit } P(y_{2it} \leq j_2 | x_{2t}) &= \alpha_{1j_2} - x'_{2it} \beta_2 + z'_{2it} u_{2i}\end{aligned}$$

and

$$\log \psi(j_1, j_2, x) = x'_{3it} \beta_3 + u_{3i}$$

where

$$\psi(j_1, j_2) = \frac{P(y_{1it} \leq j_1, y_{2it} \leq j_2 | x) P(y_{1it} \leq j_1, y_{2it} \leq j_2 | x)}{P(y_{1it} > j_1, y_{2it} \leq j_2 | x) P(y_{1it} > j_1, y_{2it} > j_2 | x)}$$

is called (global) cross ratio and u_{ki} , $k = 1, 2, 3$ are the subject specific random effects. In particular when $j_1, j_2 = 0, 1$, the model reduces to

$$\text{logit } P(y_{1it} = 1 | x_{1t}) = x'_{1it} \beta_1 + u_{1it} \quad (5)$$

$$\text{logit } P(y_{2it} = 1 | x_{2t}) = x'_{2it} \beta_2 + u_{2it} \quad (6)$$

$$\text{and } \log \psi_{it}(x) = x'_{3it} \beta_3 + u_{3it} \quad (7)$$

where $\psi(x)$ given by $\log \left(\frac{p_{00}(x)p_{11}(x)}{p_{01}(x)p_{10}(x)} \right)$ is linear in covariances and

$$p_{j_1 j_2}(x) = P(y_{1it} = j_1, y_{2it} = j_2), \quad j_1, j_2 = 0, 1.$$

The model in Eqs. 5 and 6 combined with Eq. 7 accounts for three types of associations. Firstly the association between two responses of the t th unit in the i th cluster is modeled directly through odds ratio. Secondly, the association between responses of two different units in the

same cluster occurs through the components of the vector $u_i = (u_{1i}, u_{2i}, u_{3i})'$. In the context of repeated measurements or longitudinal data. This is basically the longitudinal association. Finally the cross-sectional association between one response in one unit and other response in another unit is accommodated through u_{3i} considered in Eq. 7.

Latent Mixed Models

The primary difficulty in extending the univariate ordinal category set up is to write a flexible statistical model. In a multivariate ordinal model, responses are observed from several characteristics of a subject. Such a mixture model accommodates correlation and extravariation in the data through the involvement of a random term. Unfortunately a full likelihood analysis in such a mixture model is often hampered by the need for numerical integration. Alternatively, one can proceed through extending the idea of a latent variable-based approach to multivariate set up where a latent vector variable can be modeled. To illustrate such a model, we consider an oral hygiene study where the interest may be to see the cleaning efficacy of different toothbrushes commercially available in the market. The objective may also be to study the plaque-removing efficiency of different toothbrushes as related to factors like smoking habits, food habits, etc. Plaque formation is an important causative factor in dental caries and periodontal disease. Reduction of plaque before and after brushing is measured according to the Tureskey et al. modification, and for every subject, measurements are recorded for selected teeth which form a cluster. Further repeated measurements on each tooth of a subject may be observed across time or on application of different treatments. One can then think of a polytomous random vector $y_{ij} = (y_{ij1}, \dots, y_{ijk}, \dots, y_{ijq})$ where y_{ijk} denotes the k th categorical response of the i th subject when j th treatment is applied. Accordingly, a latent random vector $y_{ij}^* = (y_{ij1}^*, \dots, y_{ijk}^*, \dots, y_{ijq}^*)$ can be seen to act in the following way

$$\begin{aligned}y_{ij1} &= m_1 & \text{if } \alpha_{1,m_1-1} \leq y_{ij1}^* \leq \alpha_{1,m_1} \\ y_{ijq} &= m_q & \text{if } \alpha_{q,m_q-1} \leq y_{ijq}^* \leq \alpha_{q,m_q}\end{aligned} \quad (8)$$

where $1 \leq m_k \leq r_k$, $k = 1, \dots, q$ indicating that there are r_k categories for the k th variable y_{ijk} . We take $\alpha_{k,0} = -\infty$ and $\alpha_{k,r_k} = \infty$. As in the univariate setup, the latent vector is subject to a random effect model.

$$y_{ijk}^* = x'_{ijk} \beta + Z'_{ijk} u_i + \varepsilon_{ijk} \quad (9)$$

where u_i is a q -dimensional vector of random effects that take into account the cluster (subject) specific variation or longitudinal variation.

This model is basically a three-level model where i ($i = 1, \dots, n$) denote the level-3 subject, j denote the level-2 treatment for subject i and k denote the level-1 response for the i th subject in the j th occasion.

In the section “Methods for Clustered Categorical Data,” we will discuss methodologies that may be applied to draw inference from this bivariate dichotomous clustered (longitudinal) model.

METHODS FOR CLUSTERED CATEGORICAL DATA

We briefly describe here several methods for ordinal data that exhibit extra heterogeneity due to repeated measurements.

Likelihood Based Approach

A large class of model-based procedures arises from defining a model for the variables with clusters and making inferences based on maximum likelihood (ML) methods. Here one models the joint distribution by using random effects for clusters. The models have conditional interpretations with cluster (subject) specific effects. The repeated responses are typically assumed to be independent, given the random effect, but variability in the random effects induces a marginal nonnegative association between pair of responses after averaging over the random effects. Let y_i be the vector of pattern ordinal responses from subject i for all of the T occasions, then assuming independence of the responses conditional on the random effects, the conditional likelihood of any pattern y_i given u_i can be written from (2.2) as

$$L(y_i | u_i) = \prod_{t=1}^T \prod_{j=1}^C \left\{ P(y_{it} \leq j | x_{it}) - P(y_{it} \leq j-1 | x_{it}) \right\}^{d_{ij}} \quad (10)$$

where

$$d_{ij} = \begin{cases} 1 & \text{if } y_{it} = j \\ 0 & \text{otherwise.} \end{cases}$$

In fact Eq. 10 leads to the marginal likelihood as

$$L(y | \alpha, \beta) = \prod_{i=1}^n \int L(y_i | u_i) g(u_i) du_i.$$

One can either proceed through MCEM or can use Fisher scoring algorithm to obtain ML estimates. But the difficulty arises in the integration over the random effects. In order to tackle the numerical integration, required for obtaining the unconditional likelihood, several approximation inference procedures have been proposed. These include Laplace approximations of the integrated likelihood (Lin and Pierce,^[11] Solomon and Cox,^[12] Lin and Breslow^[13]), and penalized quasi likelihood (Breslow and Clayton,^[14] Schall^[15]).

In case more than one random component appears in the model, ML model fitting can be challenging. An early approach (Harville and Mee^[16]) used best linear unbiased prediction of parameters of an underlying continuous model. Because the random effects are unobserved, to obtain the likelihood function we construct the usual product of multinomials that would apply if they were known and then integrate out the random effects. Except in rare cases (see Crouchley,^[17] Tenhave^[18]) this integral does not have closed form and it is thus necessary to use some approximation for the likelihood function. We can then maximize the approximated likelihood using a variety of standard methods. For simple models like random intercept models, straightforward Gauss-Hermite quadrature is usually adequate (Hedeker and Gibbons^[7,19]). An adaptive version of Gauss-Hermite quadrature (e.g., Lin and Pierce,^[20] Pinheiro and Bates^[21]) uses the same weights and nodes for the finite sum as Gauss-Hermite quadrature, but to increase efficiency, it centers the nodes with respect to the mode of the function being integrated and scales them according to the estimated curvature at the node. For models with higher dimensional integrals, more feasible methods use Monte Carlo (MC) methods which use the randomly samples nodes to approximate integrals. Booth and Hobert^[22] proposed an automated MCEM algorithm that assesses the MC error in the current parameter estimates and increases the number of nodes if the error exceeds the change in the estimates from the previous iteration.

Bayesian Approach

There have been several studies on the Bayesian estimation of cell probabilities in contingency tables (Good,^[23] Fienberg and Holland,^[24,25] Agresti and Chung,^[26] Some Bayesian (Evans et al.,^[27] Kateri et al.^[28]) later stressed estimation of association parameters. In this review, we emphasize the Bayesian approach for analyzing ordinal response data. One of the most important contributions is by Johnson.^[29] In the cumulative link models, they considered beta prior distributions for the cumulative probabilities at several values of the explanatory variables. The hybrid Metropolis-Hasting's/Gibbs sampler they used for fitting takes into account the ordering restriction on the intercept $\{\alpha_j\}$ parameters without any difficulty.

Chipman and Hamada^[30] carried out Bayesian analysis for a cumulative probit model. Bayesian ordinal models with latent mixed regression have been addressed earlier by Albert and Chib,^[31] Johnson.^[32] Other literature on Bayesian analysis with ordinal responses include Bradlow and Zaslarsky,^[33] Biswas and Das,^[34] Cowles et al.,^[35] Ishwaran and Zarepour,^[36] Ishwaran and Gatsonis,^[37] Tan et al.,^[38] Rossi et al.^[39]

Bayesian clustered ordinal data analysis has received attention for the last few years. Chib and Grenberg^[40] considered a multivariate normal latent random vector to define

the categories of the discrete variables repeatedly observed over time or over clusters. Recently O'Brien and Dunson^[41] formulated a multivariate logistic distribution in a very elegant manner where the correlation parameters are directly involved. Webb and Forster^[42] proposed a model where the conditional posterior of distributions are standard and simulations are easy. Chen and Shao^[43] employed a scale mixture of multivariate normal links and established condition for propriety under noninformative priors. Tan et al.^[38] generalized the methodology in Qu and Tan^[44] to propose Bayesian hierarchical proportional odds model with a complex random effect structure for three levels data, allowing each cluster to have a different number of observations. They used a MCMC fitting method that avoids numerical integration to estimate the fixed effects and the correlation parameters.

GEE Approach

GEE provides a non-likelihood based approach for fitting models for repeated or clustered ordinal data. This method seems to be useful as often in ML fitting of the marginal model though it is sometimes quite difficult to maximize the log-likelihood function. The GEE methodology originally specified for marginal GLM, extends to cumulative logit models^[45] and cumulative probit models^[46] for repeated ordinal responses. Though computationally GEE approach is much simpler than the full likelihood based approach, one naturally loses information to some extent by just relying on the first two moments. In fact, it really loses significant amount of information unless the sample size is extremely large.

ANALYSIS OF CLUSTERED MULTIVARIATE ORDINAL MODELS

Analysis of Dale's Model for Binary Set Up

In the following two subsections "Classical Likelihood Based Analysis" and "Bayesian Analysis," we would consider analysis of Dale's likelihood base correlated binary model under the classical and Bayesian framework.

Classical Likelihood Based Analysis

Following the previous notations for correlated binary models in Eqs. 5–7 under the assumption that $u_i \sim N_{3T}(0, \Sigma)$ for all i , we write the likelihood as

$$\ell(\psi/\text{data}) \propto \prod_i \int \ell_{ic}(\psi) du_i \quad (11)$$

where the parameter vector ψ consists of $\beta = (\beta'_1, \beta'_2, \beta'_3)'$ and those nuisance parameters that appear in Σ . Further the complete data likelihood corresponding to subject i is

$$\ell_{ic}(\Psi/\text{data}) = \prod_{t=1}^T \prod_{r=0}^1 \prod_{m=0}^1 p_{rmit}^{\tilde{y}_{rmit}} \quad (12)$$

where

$$p_{1it} = \frac{a_{it} - \sqrt{a_{it}^2 + c_{it}}}{2(\xi_{it} - 1)} \quad \text{if } \xi_{it} \neq 1$$

$$= p_{1it} p_{2it} \quad \text{if } \xi_{it} = 1$$

$$a_{it} = 1 + (p_{1it} + p_{2it})(\xi_{it} - 1), c_{it} = -4\xi_{it}(\xi_{it} - 1)p_{1it}p_{2it}$$

and

$$z_{rmit} = y_{1it}^1 y_{2it}^m (1 - y_{1it})^{1-r} (1 - y_{2it})^{1-m}, \quad r, m = 0, 1.$$

In view of the difficulty in evaluating the integrals, one can proceed through Monte Carlo EM (MCEM) to estimate the parameters. Note that Tenhave and Morabia^[47] considered a particular setup where they introduced standard deviations as a coefficient corresponding to the random components u_1 , u_2 , and u_3 in Eqs. 5–7 and assumed b_{ik} 's ($k = 1, 2, 3$) to be standard normal deviate vector.

The model in Eqs. 5–7 is more general as the assumption of dispersion matrix helps to study the longitudinal dependence (see Naskar and Das^[48] for more discussion). Numerical studies in this regard have been carried out in the section "Illustrative Example." Normality assumption of the random effects, though a bit convenient mathematically, may not always hold. In fact such an assumption fails to accommodate multimodality, skewness, and heavy-tailed features of the distribution of random effects. A very general class of mixing could be considered by introducing nonparametric Dirichlet process for unknown distribution of the random effects. The resulting semiparametric correlated binary model, though computer intensive, is capable of providing more accurate inference when the heterogeneity in the data exhibits multimodality/skewness/heavy-tailed features.

Bayesian Analysis

For the correlated binary set up in Eqs. 5–7, a Bayesian semiparametric model can be formed by presenting the hierarchical priors for p -dimensional fixed effects β . Writing $\mathbf{d} = (d_1, \dots, d_p)'$ and $\sigma = (\sigma_1^2, \sigma_2^2, \dots, \sigma_p^2)'$, we choose the priors.

$$\beta|\mathbf{d}, \sigma \sim N_p(\mathbf{d}, \text{diag}(\sigma)) \quad (13)$$

$$d_r|\sigma_b^2 \stackrel{iid}{\sim} N(0, \sigma_{ob}^2), \quad r = 1, 2, \dots, p$$

$$\sigma_r^2|s_1, s_2 \stackrel{iid}{\sim} \text{Gamma}(s_1, s_2), \quad r = 1, 2, \dots, p$$

where $\text{diag}(\sigma) = \text{diag}(\sigma_1^2, \dots, \sigma_p^2)$.

Further we assume

$$\mathbf{u}_i \stackrel{iid}{\sim} G, G \sim DP(\alpha G_0) \quad (14)$$

The unknown distribution G of $\mathbf{u}_i$ is assumed to have a Dirichlet process prior where the base measure G_0 can be thought of as a guess of the distribution of random effects and α as a measure of the strength of this belief.

The full Bayesian model in the present context is completed by the prior assumptions on α and G_0 . It is assumed that

$$\alpha | \gamma_1, \gamma_2 \sim \text{Gamma}(\gamma_1, \gamma_2), G_0 | \Sigma \sim N_{3T} \left(0, \Sigma \right)$$

where the baseline covariance matrix Σ is

$$\begin{aligned} \Sigma &= \text{Block diag} \left(\Sigma_1, \Sigma_2, \Sigma_3 \right), \\ \Sigma_k &= \sigma_{ok}^2 \left[(1 - \rho_k) I_T + \rho_k \mathbf{1}_T \mathbf{1}_T' \right], \quad k = 1, 2, 3. \\ \mathbf{1}_T &= (1, \dots, 1)' \end{aligned}$$

The full conditionals can be derived as follows

$$\beta | \mathbf{d}, \sigma, \mathbf{u}, \text{data} \propto \ell_c \times \text{Diag}(\sigma) \quad (15)$$

where $\ell_c = \prod_{i=1}^n \ell_{ic}$, ℓ_{ic} is given in Eq. 12

$$\mathbf{d} | \beta, \sigma \sim N_p(\Delta^* \text{Diag}(\sigma^{-2}) \beta, \Delta^*) \quad (16)$$

where $\Delta^* = (\text{Diag}(\sigma^{-2}) + \sigma_{ou}^{-2} I)^{-1}$, $\text{Diag}(\sigma^{-2}) = \text{diag}(\sigma_1^{-2}, \dots, \sigma_p^{-2})$

Further, for $\ell = 1, \dots, p$.

$$\sigma_\ell^{-2} | \beta, \mathbf{d}, \stackrel{iid}{\sim} \text{Gamma} \left(s_1 + \frac{1}{2}, s_2 + \frac{(\beta_\ell - d_\ell)^2}{2} \right) \quad (17)$$

and marginalizing over G , the predictive distribution of $\mathbf{b}$ is

$$\begin{aligned} \mathbf{u} | \beta, \alpha, \theta &\propto \prod_{i=1}^n \ell_{ic} \\ &\times \prod_{i=1}^n \left\{ \frac{\alpha}{\alpha + i - 1} g_0(\mathbf{u}_i | \theta + \frac{1}{\alpha + i - 1} \sum_{j=1}^{i-1} \gamma_{ji} \delta_{uj}(\mathbf{u}_i)) \right\} \end{aligned} \quad (18)$$

where $g_0(\cdot | \theta)$ is the baseline density indexed by the parameter (vector) θ , γ_{ji} is the number of $\mathbf{u}_{j'}$, $j' = 1, \dots, i-1$

such that $\mathbf{u}_i = \mathbf{u}_{i'}$ and $\delta_x(\cdot)$ is a function concentrated at x . Carrying out a component-wise MH algorithm within Gibbs sampler, we can generate samples from Eqs. (4.7)–(4.10) and hence make necessary posterior inferences.

Analysis of Latent Mixed Model

In view of Eqs. 8 and 8, conditional on $\mathbf{u}_i$, we compute

$$\begin{aligned} P^{u_i} &= P(y_{i1} = m_1, \dots, y_{iq} = m_q | \mathbf{u}_i) \\ &= P^{u_i}(\alpha_1, m_1 - 1 \leq y_{i1}^* < \alpha_{1,m_1}, \dots, \alpha_{q,m_q-1} \\ &\leq y_{iq}^* < \alpha_{q,m_q}) \\ &= \prod_{k=1}^q P^{u_i}(\alpha_{k,m_k-1} \leq y_{ik}^* < \alpha_{k,m_k}) \\ &= \prod_{k=1}^q P_k^{u_i}. \end{aligned}$$

Thus conditionally given $\mathbf{u}_i$, the likelihood is

$$\begin{aligned} \ell^{u_i} &= \prod_{t=1}^T \sum_{m_q=1}^{r_1} \dots \sum_{m_q=1}^{r_q} 1_{m_1, \dots, m_q}^{it} P^{u_i} \\ &= \prod_{t=1}^T \left[\sum_{s=1}^q \sum_{m_s=1}^{r_s} 1_{m_1, \dots, m_q}^{it} \prod_{k=1}^q P^{u_i} \right] \\ &= \prod_{t=1}^T \left[\sum_{s=1}^q \sum_{m_s=1}^{r_s} 1_{m_1, \dots, m_q}^{it} 1_{m_1, \dots, m_q}^{*it} \prod_{k=1}^q \phi(x'_{ik} \beta + Z'_{ik} \mathbf{u}_i, 1) \right] \end{aligned}$$

where ϕ is the normal pdf and

$$\begin{aligned} 1_{m_1, \dots, m_q}^{it} &= 1 \text{ if } y_{i1} = m_1, \dots, y_{iq} = m_q \\ &= 0 \text{ otherwise} \\ 1_{m_1, \dots, m_q}^{*it} &= 1 \text{ if } y_{i1}^* = m_1, \dots, y_{iq}^* = m_q \\ &= \text{otherwise.} \end{aligned}$$

In fact the unconditional likelihood is

$$L = \prod_{i=1}^n \int_{\mathbf{u}_i} \ell^{u_i} g(\mathbf{u}_i) d\mathbf{u}_i$$

where $g(\mathbf{u}_i)$ is the pdf of $\mathbf{u}_i$.

Because the likelihood involves high dimensional integration, no analytically tractable form can be obtained. One way to obtain the maximum likelihood estimate (MLE) is to proceed through multidimensional Gauss-Hermite Quadrature for integration (Liu and Hedeker^[8]). But that also creates difficulty in case of high dimension integration. Alternatively, we can proceed by using MCEM technique. In the section “Illustrative Example” we provide the estimates based on this technique.

Bayesian Analysis

Assume that the random component $u_i \sim N_q(0, \Sigma)$, $i = 1, \dots, n$. For the model Eqs. 8 and 9, the following prior is then assumed

$$\begin{aligned} \pi\left(\beta, \sum\right) &\propto \pi(\beta) \pi\left(\sum\right) \\ \beta &\sim N_p\left(0, \sum_0\right) = \text{diag}(\sigma_0^2) \\ \sigma^2 &\sim \phi_k\left(\sigma \mid \sigma_0, T_0^{-1}\right), \sigma \in \wp \end{aligned}$$

where $\sigma = (\sigma_{12}, \dots, \sigma_{q-1,q})'$ are the distinct $q/2(q-1)$ elements of Σ . Note that in order to avoid non-identifiability without loss in generality, we assume Σ to be a correlation matrix. Further we choose the prior for σ to be a truncated $N_k(\sigma_0, T_0^{-1})$ where the truncated region $\wp \subset S = [-1, 1]^{q(q-1)/2}$. One can then apply MH algorithm within the Gibbs sampler to generate observations from the full conditionals (see Das and Chattopadhyay^[49]). A general Bayesian semiparametric analysis could be done where u_i assumed to have some unknown distribution G . The following priors are considered.

$$\begin{aligned} \beta &\sim N_p\left(0, \sum_0\right), \quad G \sim DP(\alpha G_0) \\ G &\sim N_q\left(0, \sum\right), \quad \sum \sim W_q(\gamma, R) \end{aligned}$$

where G refers to a random distribution generated by a Dirichlet process with base distribution G_0 and total mass parameter α (known), γ and R , respectively, the degrees of freedom and known covariance matrix associated with the inverted Wishart prior. A key feature is that $u_i s'$ are marginally samples from G_0 and with positive probability some of the $u_i s'$ are identical. This is because of discreteness of the random measure G . The full conditionals for such model can be derived as follows.

$$\begin{aligned} \left[\beta \mid \sum, u, y^*, y\right] &\sim N_\phi\left(\hat{\beta}, (x'x)^{-1}\right) \\ \left[\sum \mid \beta, u, y^*, y\right] &\sim w_q(v + v_0, (R^{-1} + uu')^{-1}) \\ \left[y_{ik}^* \mid \beta, \sum, u, y_{-ik}^*\right] &\sim N(x_{ik}'\beta + u_{ik}, 1) \quad \alpha_{m_k-1} \leq y_{ik}^* < \alpha_{m_k} \\ \left[u_i \mid \beta, \sum, u_{-i}, y, y^*\right] &\propto \left(\sum_{j \neq i} e^{-\frac{1}{2}(y_i^* - x_i\beta)' V_i (y_i^* - x_i\beta)} \times \delta u_j(u_i)\right) \\ &\quad + |Q_i|^{-1/2} \left|\sum\right|^{-1/2} \int e^{-1/2(y_i^* - x_i\beta)' (y_i^* - x_i\beta)} du_i \\ &\quad \times g(u_i \mid 0, \sum) f(y_i^* \mid u_i, \beta, y, y_{-j}^*) \end{aligned}$$

where v_0 is the number of distinct $u_i s'$, $Q_i = (\Sigma^{-1} + Z_i'Z_i)^{-1}$, $V_i = Z_i Q_i Z_i' - I$ and u_{-i} , denote the random effects for

subjects excluding subject i . Note that $\delta_s(\cdot)$ is a degenerate distribution with mass point s and c is a constant.

ILLUSTRATIVE EXAMPLE

Example 1: Tibolone Data

To examine the performance and compare classical approach (both with and without random effects) and Bayesian approach for the correlated binary models, we consider a data on 200 women who have undergone Hormone Replacement Therapy. The primary objective in this study was to see whether tibolone is effective for reducing physiological problems like hot flashes (HF) and vaginal dryness (VD). The effectiveness of tibolone is, in fact, neglected through these pair of responses, collected as “mild” or “severe” corresponding to those two symptoms. The responses on these symptoms were observed at pre-treatment stage and after every 30 doses in a period of three months. The age and number of doses (NOD) considered to be covariates play important role on the effectiveness of tibolone. Empirical study revealed (see Naskar and Das^[48]) the following correlated binary model (CBM) conditional on the random components u_{kit} , $k = 1, 2, 3$

$$\begin{aligned} \text{logit}(p_{kit}) &= \beta_{k0} + \beta_{k1}(\text{age})_{it} + \beta_{k2}(\text{NoI})_{it} \\ &\quad + \beta_{k3}(\text{NoD})^2 + u_{kit}, \quad k = 1, 2 \end{aligned}$$

$$\text{log}(\xi_{it}) = \beta_{30} + \beta_{31}(\text{age})_{it} + \beta_{32}(\text{NoD})_{it} + u_{3it}.$$

Table 1 gives the result obtained by likelihood based MCEM approach in the classical paradigm and also the full Bayes Gibbs sampling approach in the Bayesian paradigm. In both the classical and Bayesian set up, we have considered DP mixing of CBM to account for all possible types of heterogeneity. For the Bayesian approach the posterior mean and standard errors are computed by generating observations from the full conditionals. One can also compute the 95% confidence interval or the predictive interval for the parameters of interest.

Simulation Study

An extensive investigation has been carried out to study the finite sample performances of the ML and Bayes estimates in CBM. Assume a single covariate x_{10it} for the first marginal model, x_{20it} , x_{21it} second marginal model and x_{30it} for the log association model. The covariates x_{20it} , x_{21it} and x_{30it} are generated from a standard normal variate and the covariate effect x_{21it} is generated from $U[-1, 1]$. To simulate two-level bivariate binary data, we take for $i = 1, \dots, 50$, $t = 1, \dots, 4$.

$$u_i \sim G, G \mid G_0 \sim DP(\alpha G_0), G_0 = N_{12}\left(0, \sum\right) \quad (19)$$

^aValues obtained under ML method^bValues obtained under Bayesian approach with normality of random effect^cValues obtained under DP mixed Bayesian model

where

$$\Sigma = \text{block diag}(\Sigma_1, \Sigma_2, \Sigma_3), \Sigma_k = 2[.5I_4 + .51_41_4'] \\ k = 1, 2, 3.$$

We also take $\alpha = 1.0$. Then the bivariate binary data set is formed by first generating u_i 's from Eq. 19 according to Polya urn-based algorithm (Blackwell and McQueen^[50]) and then following models Eqs. 5–7 with $\beta_{10} = \beta_{30} = \beta_{21} = 1.0$ and $\beta_{20} = 0.5$. ML estimates obtained under this simulated data set by using MCEM are given in Table 2. In the Bayesian context we consider the prior hyperparameters $\sigma_0 = 10$, $s_1 = s_2 = 0.001$. To ensure regularity on the influence of small as well as large values of α we choose hyperparameters $\gamma_1 = \gamma_2 = 2.0$ in the gamma prior for α . Table 2 lists the estimates and their standard errors obtained by the likelihood approach and the Bayesian approach under DP mixing and simple normal mixing.

Oral Hygiene Data

In order to compare the cleaning efficacy of different designs of toothbrushes, a survey was conducted of 220 students and staff members from hospitals in and around Kolkata. A detailed history for each sample individual recorded a week prior to the beginning of the study to collect information like age, sex, occupation, food habit, smoking habit, and teeth-cleaning habit. The amount of plaque on the facial and lingual surfaces of 6 selected teeth for each individual was scored according to the Turesky et al.^[51] modification of the Quigley-Hein index. Each individual was given a total of six different designs of toothbrushes to be used during the four-month long clinical study (see Das and Chattopadhyay^[49] for details). Final data set essentially based on a cross over trial, provided the differences of pre- and post-brushing scores for 220 individuals corresponding to six different types of brushes. Table 3 compares the result

ML—likelihood-based MCEM approach, FB—full Bayesian-Gibbs sampler, and DPB—Dirichlet process-based Bayesian approach.

obtained by likelihood based MCEM approach (where $u_i \sim N(0, 0.51 \pm 0.511')$ discussed in the previous section and by the full Bayes with hyperparameter approach ($\sum_0 = \sigma_0^2 I$, $\sigma_0 = 10$, and $T_0 = I$) and the DP mixed Hierarchical Bayes approach (with $v = 10$, $R = 0.1I + 0.911'$) discussed in the section “Bayesian Analysis.” The details of the computations have been demonstrated in Das and Chattopadhyay.^[49] The study revealed that the plaque formation rate is higher for smokers and nonvegetarians. Also, the cleaning efficacy of a certain brush is likely to be the best among all brands of brushes.

DISCUSSION

In view of the computational advances, it is now possible to encompass a much broader area of techniques for the analysis of categorical data.^[52–54] Though chi-square and unconditional logistic regression methods still comprise the staple diet for analysis by the health science researchers, recently developed methods for ordinal data analysis are receiving wider use. Furthermore, complex data sets involving cluster samples with discrete and continuous multilevel covariates are being analyzed these days by using sophisticated tools leading to exact inference. This survey describes recent enhancements in the area of clustered categorical data analysis and discusses several applications of the recent methodology. One possible direction would be to analyze multivariate repeated measurements (or clustered) data is to proceed through the latent vector approach. However, the association among the variable of a subject is not truly exposed. Alternatively, one can proceed by developing a multivariate association model. In this survey we discuss this kind of models in the bivariate setup. We also have discussed the limitations considering the normality assumption of the subject specific effects and proposed some nonparametric distribution instead. The analysis of clustered categorical data using the Bayesian

approach specification of prior distribution still remains a problem.

As emphasized in our discussion, we believe there is a great need for further studies in clustered data with multivariate responses both from analysis and design viewpoints. The analysis of multilevel models needs to be developed further. In the regression setup, it may be of interest to look into the properties of regression parameters, especially when the nonparametric distribution of the random effects are considered.

Most methodologies discussed here have appeared in the last few years and have yet to be disseminated among the health science/social science researchers. We hope that computational advances will continue expanding the scope of exact methods and that complex data sets will more commonly be analyzed by statistical methods that incorporate various patterns of depending in the data.

Analysis of Heritability

Brent D. Burch

U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Ian R. Harris

Southern Methodist University, Dallas, Texas, U.S.A.

Abstract

The heritability of a measurable characteristic is the most commonly used statistic for expressing the degree to which genetic material is transferred from parent to progeny. This entry reviews methods of analyzing heritability such as statistical modeling and point and interval estimation.

INTRODUCTION

Statistical methods applied to the field of quantitative genetics provide insight concerning the role that nature and nurture play in the development of life forms. Physical traits of organisms depend on genetic as well as environmental influences and quantifying these effects are major concerns in the study of plants, animals, and human beings. The heritability of a measurable characteristic is the most commonly used statistic for expressing the degree to which genetic material is transferred from parent to progeny. Heritability is defined in terms of the variation in the trait under study and relies on the partitioning of this variation into components that are attributable to genetic and environmental sources. Variance components in mixed linear models are used to measure how different sources contribute to the variation of a characteristic.

Statistical models serve as the basis for analyzing heritability. The analysis of heritability is accomplished by measuring the trait of interest, and other important variables, on a collection of subjects. In addition, the relationships among the subjects are recorded and used in the statistical model. These relationships provide information about the pedigree structure or lineage of the subjects. Point estimators, confidence intervals, and hypothesis tests are some of the statistical inferential procedures employed to analyze heritability.

HERITABILITY

The phenotype of an individual is a quantitative characteristic or trait that is the result of combined influences of genetic and nongenetic effects. In equation form,

$$P = G + E \quad (1)$$

where P is the phenotypic value, G is the genotypic value which represents the effect of the set of genes that contribute to the phenotypic value, and E is the environmental (nongenetic) effect on the phenotypic value. The genotypic value (G) is further partitioned into distinct genetic effects. Specifically,

$$G = A + D + I \quad (2)$$

where A is the additive genetic effect, D is the dominance genetic effect, and I is the epistatic or interaction genetic effect. The additive genetic effect (A) represents that part of G which is transferable from one generation to the next. In some applications, A is referred to as the breeding value of the individual because it is the primary factor in determining the resemblance between relatives. The dominance genetic effect (D) is a result of the dominance of alleles at a locus. In other words, D represents the interaction of alleles within a locus or within-locus interactions. The epistatic genetic effect (I) accounts for genotypic values that depend on more than one locus. Genes are said to be epistatic if the effects of the different loci are not independent. The overall genotypic value for an individual is determined by the sum of the effects of the individual loci.

Heritability is defined in terms of the variances associated with the genetic influences on the phenotypic value. If $\text{Var}(G)$ and $\text{Var}(P)$ are the variances of the genotypic and phenotypic values, respectively, then heritability in the broad sense is defined as

$$H^2 = \frac{\text{Var}(G)}{\text{Var}(P)} \quad (3)$$

H^2 is the proportion of the total phenotypic variance attributable to genetic effects. H^2 is sometimes referred to as the coefficient of genetic determination. The more

commonly used form of heritability is known as heritability in the narrow sense. If $\text{Var}(A)$ is the variance of the additive genetic effect, then heritability in the narrow sense is defined as

$$h^2 = \frac{\text{Var}(A)}{\text{Var}(P)} \quad (4)$$

and is the proportion of the total phenotypic variance resulting from additive genetic effects. The coefficient h^2 measures the importance of transmissible genetic material because it quantifies to what extent the variation in the phenotype of a progeny is determined by the genes transmitted from its parents. See Refs. [1–4] for a thorough discussion of heritability and quantitative genetics.

In the analysis of h^2 , the primary source of variation under study is that which results from additive genetic effects. The other sources of variation (environmental, dominance, epistatic) play a secondary role and are often combined into a single term. In this manner

$$\begin{aligned} P &= A + (D + I + E) \\ &= A + \text{Other} \end{aligned} \quad (5)$$

so that

$$\text{Var}(P) = \text{Var}(A) + \text{Var}(\text{Other}) \quad (6)$$

with the understanding that additive genetic effects and the other effects combined are treated as uncorrelated. In most applications, h^2 is written in terms of variance components. Variance components correspond to the sources that produce variation in the phenotypic value. If

$$\text{Var}(A) = \sigma_1^2 \quad (7)$$

and

$$\text{Var}(\text{Other}) = \sigma_2^2 \quad (8)$$

it follows that heritability (in the narrow sense) is a function of σ_1^2 and σ_2^2 , say, $h^2 = f(\sigma_1^2, \sigma_2^2)$, where

$$h^2 = \frac{\sigma_1^2}{\sigma_1^2 + \sigma_2^2} \quad (9)$$

This form of h^2 enables the investigator to utilize statistical models to analyze heritability. See Refs. [5–7] for further details concerning statistical models involving genetic variances.

STATISTICAL MODELING OF HERITABILITY

The statistical models used to analyze heritability contain the effects that influence the quantitative characteristic

under study. Effects have different values of interest called levels. If all levels of an effect are included in a model, or only those particular levels of an effect included in the model are of interest, the effect is called a fixed effect. Gender (Male, Female) and smoking status (Yes, No) are examples of fixed effects. If the levels of an effect included in the model may be considered as a random sample of all possible levels, the effect is called a random effect. The additive genetic effect is considered random if the subjects in the study are a random sample from a population of subjects. In this scenario, the focus of attention is not on the specific levels of the effect but on the underlying distribution of the random effect. In particular, the variance of the random effect, for example, the variance of the additive genetic effect, is used to measure the contribution of the effect on the overall variation of the characteristic under study.

Mixed linear models, models that include a linear combination of fixed and random effects, are used in the analysis of heritability. Using matrix notation,

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u} + \boldsymbol{\varepsilon} \quad (10)$$

where $\mathbf{Y}$ is the vector of measured characteristics, $\boldsymbol{\beta}$ is the vector of parameters associated with the fixed effects, $\mathbf{u}$ is the vector of unobservable additive genetic effects, and $\boldsymbol{\varepsilon}$ is the vector of unobservable random variables corresponding to “other” effects as given in Eq. 5. For a particular individual, Y_i is the phenotypic value, $x_i'\boldsymbol{\beta}$ is the mean phenotypic value for members of the population associated with x_i where x_i is the i th row of $\mathbf{X}$, u_i is the additive genetic effect, and ε_i represents the combined effect of sources of variation in the phenotypic value not accounted for by the additive genetic effect.

For the purpose of statistical inference, it is assumed that $\mathbf{u}$ and $\boldsymbol{\varepsilon}$ are independent and multivariate normally distributed. Specifically, $\mathbf{u} \sim N(0, \sigma_1^2 \mathbf{R})$ and $\boldsymbol{\varepsilon} \sim N(0, \sigma_2^2 \mathbf{I})$ where the matrix $\mathbf{R}$ is referred to as the relationship matrix and $\mathbf{I}$ is the identity matrix. It follows that $\mathbf{Y} \sim N(\mathbf{X}\boldsymbol{\beta}, \mathbf{V})$ where

$$\mathbf{V} = \sigma_2^2 \mathbf{I} + \sigma_1^2 \mathbf{Z}\mathbf{R}\mathbf{Z}' \quad (11)$$

The matrix $\mathbf{R}$ describes the degree to which the subjects in the study are genetically related.

Consider a simple example of the modeling process. Suppose the phenotypic values of six subjects have been recorded. The gender (M,F) and the relationships among the six subjects are displayed in Fig. 1. For instance, subject 1 is a male having a son (subject 3), a daughter (subject 4), and a grandson (subject 6). Note that the parents of subjects 1 and 2 have not been recorded, and subjects 3, 4, 5, and 6 have only one identifiable parent each. Based on Fig. 1, one can also see that subjects 1 and 2 are unrelated and thus the offspring of subject 1 will be unrelated to the offspring of subject 2.

Fig. 1 Pedigree structure

Let Y_i be the phenotypic value of the i th subject, $i = 1, \dots, 6$. Then $\mathbf{Y}' = [Y_1, Y_2, Y_3, Y_4, Y_5, Y_6]$ is the vector of responses for the subjects. The mixed linear model for this example may be expressed as

$$\begin{bmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \\ Y_5 \\ Y_6 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 0 \\ 0 & 1 \\ 1 & 0 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} \beta_1 \\ \beta_2 \end{bmatrix} + \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ & 1 & 0 & 0 & 0 & 0 \\ & & 1 & 0 & 0 & 0 \\ & & & 1 & 0 & 0 \\ & & & & 1 & 0 \\ & & & & & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \\ u_5 \\ u_6 \end{bmatrix} + \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \\ \varepsilon_6 \end{bmatrix} \quad (12)$$

The influence of the fixed effect gender on the responses is taken into account by the 2×1 vector β , where the first element of β corresponds to males and the second element of β corresponds to females. The influence of additive genetic effects on the responses is taken into account by the vector 6×1 vector u . The additive genetic effect is a random effect in this example.

From Fig. 1, subjects 1, 3, 4, and 6 are related and subjects 2 and 5 are related. The relationship matrix $\mathbf{R}$ for the example is

$$\mathbf{R} = \begin{bmatrix} 1 & 0 & 1/2 & 1/2 & 0 & 1/4 \\ & 1 & 0 & 0 & 1/2 & 0 \\ & & 1 & 1/4 & 0 & 1/2 \\ & & & 1 & 0 & 1/8 \\ & & & & 1 & 0 \\ & & & & & 1 \end{bmatrix} \quad (13)$$

Because subject 3 receives one-half of its genetic material from subject 1 (the other half coming from an unidentified source), the genetic covariance between subjects 1 and 3, denoted by $\text{Cov}(u_1, u_3)$, is $1/2\sigma_1^2$. Similarly, because subjects 3 and 4 are half-sibs, that is, they have only one parent in common, $\text{Cov}(u_3, u_4) = 1/4\sigma_1^2$. Note, for instance, that $\text{Cov}(u_1, u_5) = 0$ as subjects 1 and 5 do not share any

common genetic material. A general procedure used to construct the relationship matrix is given in Ref. [8].

Heritability of the characteristic under study is based on the variance components in the statistical model. It is assumed that $\sigma_1^2 \geq 0$ and $\sigma_2^2 > 0$. This setup allows for the possibility that the genetic influence on the variability in the phenotypic value may be negligible. It follows, from Eq. 9, that $0 \leq h^2 < 1$. In the following three sections, the analysis of heritability is considered by applying the statistical inferential procedures of point estimation, interval estimation, and hypothesis testing.

POINT ESTIMATION

The point estimation techniques used for h^2 are essentially the same as those used to estimate the individual variance components. That is, if $\hat{\sigma}_1^2$ and $\hat{\sigma}_2^2$ are the estimates of σ_1^2 and σ_2^2 , respectively, then $\hat{h}^2 = f(\hat{\sigma}_1^2, \hat{\sigma}_2^2)$, where

$$\hat{h}^2 = \frac{\hat{\sigma}_1^2}{\hat{\sigma}_1^2 + \hat{\sigma}_2^2} \quad (14)$$

is the estimate of h^2 . In this section, we discuss estimators based on analysis of variance (ANOVA), maximum likelihood (ML), and restricted maximum likelihood (REML) procedures. Because ML estimators are translation invariant, the properties of the ML estimators of h^2 carry over from the properties of the ML estimators of σ_1^2 and σ_2^2 . In addition to the estimators considered here, alternative estimators of h^2 may be of interest.

Analysis of Variance Estimation

The ANOVA estimator of h^2 may be obtained from the ANOVA table associated with the model. The procedure involves equating the sums of squares to their expected values and solving for the estimates of the resulting variance components. In general, if $\mathbf{B}_i$ is a symmetric matrix having the same dimension as the length of the $\mathbf{Y}$ vector, then the expected value of $\mathbf{Y}'\mathbf{B}_i\mathbf{Y}$ is

$$E(\mathbf{Y}'\mathbf{B}_i\mathbf{Y}) = \text{tr}(\mathbf{B}_i\mathbf{V}) + \beta' \mathbf{X}'\mathbf{B}_i\mathbf{X}\beta \quad (15)$$

$\text{tr}(\mathbf{B}_i\mathbf{V})$ is the trace of the matrix $\mathbf{B}_i\mathbf{V}$ and is a linear combination of the variance components. The expectation will be free of the fixed effects β if $\beta' \mathbf{X}'\mathbf{B}_i\mathbf{X}\beta$ is zero. There exists a $\mathbf{B}_i$ such that

$$E(\mathbf{Y}'\mathbf{B}_i\mathbf{Y}) = r_i\sigma_2^2 + r_i\lambda_i\sigma_1^2 \quad (16)$$

where $0 \leq \lambda_1 < \dots < \lambda_d$ are the distinct eigenvalues, each having multiplicity r_i , of a matrix related to the $\mathbf{B}_i$'s. See Ref. [9] for more details. Under normal theory the quadratic forms, $\mathbf{Y}'\mathbf{B}_i\mathbf{Y}$, more simply written as Q_i , are

independently distributed as $(\sigma_2^2 + \lambda_i \sigma_1^2) \chi^2$ variates with degrees of freedom r_i .

In many applications $\lambda_1 = 0$, which implies that replications exist in the experiment. The ANOVA table associated with this scenario is given in Table 1.

For those applications in which $\lambda_1 > 0$, there is not a simple estimator of σ_2^2 . In either case, the ANOVA estimator of h^2 takes the form of

$$\hat{h}^2 = \frac{\sum_{i=1}^k r_i \sum_{i=k+1}^d Q_i - \sum_{i=k+1}^d r_i \sum_{i=1}^k Q_i}{\sum_{i=k+1}^d r_i (\lambda_i - 1) \sum_{i=1}^k Q_i - \sum_{i=1}^k r_i (\lambda_i - 1) \sum_{i=k+1}^d Q_i} \quad (17)$$

where the choice of k represents the partitioning of $Q_1, \dots, Q_d$ into two distinct groups and lies at the discretion of the investigator. Only for the case when $d = 2$ is the ANOVA estimator of h^2 unique. This occurs when the model is based on balanced data. Note that $0 \leq h^2 < 1$ whereas $\hat{h}^2$ may be negative.

Maximum Likelihood and Restricted Maximum Likelihood Estimation

The ML and REML procedures estimate variance components, and hence heritability, by determining the values of the variance components that maximize a likelihood function based on the response vector $\mathbf{Y}$. ML methods require the investigator to specify the distribution of the responses and, in many applications, it is assumed that $\mathbf{Y}$ is multivariate normally distributed. The ML estimation procedure uses a likelihood function that is based on the original responses and produces estimates of β in addition to estimates of σ_1^2 and σ_2^2 . The logarithm of the likelihood function, which is the function that is usually maximized to obtain the ML estimators, is often denoted by $L(\beta, \sigma_1^2, \sigma_2^2 | \mathbf{Y})$. The ML estimate of heritability may be obtained by first estimating the variance components and then using Eq. 14.

The REML estimation procedure uses a likelihood function that is based on a transformation of the responses. The distribution of the transformed responses, also referred to as error contrasts, does not depend on the fixed effects part of the model in Eq. 10. The logarithm of the likelihood function for REML estimation can be written as $L(\sigma_1^2, \sigma_2^2 | \mathbf{Q})$ where $\mathbf{Q}$ is the vector $(Q_1, \dots, Q_d)$. The elements of $\mathbf{Q}$ represent the squares of the error contrasts.

Table 1 ANOVA Table

Source	df	SS	E(SS)
Model (free of β)	$\sum_{i=2}^d r_i$	$\sum_{i=2}^d Q_i$	$\sigma_2^2 \sum_{i=2}^d r_i + \sigma_1^2 \sum_{i=2}^d r_i \lambda_i$
Error	r_1	Q_1	$r_1 \sigma_2^2$

It follows that the REML procedure is used to estimate the variance components only. By applying Eq. 14, one obtains the REML estimate of heritability. See the *Mixed Effects Model* entry for more information concerning ML procedures in mixed linear models.

By construction, both the ML methods result in estimates of heritability that are in the parameter space. That is, $0 \leq \hat{h}_{\text{ML}}^2 < 1$ and $0 \leq \hat{h}_{\text{REML}}^2 < 1$. Whereas the REML estimation procedure accounts for the degrees of freedom that are associated with estimating fixed effects, the ML estimation procedure does not. For all but the simplest of models, closed-form expressions for the ML and REML estimators do not exist and iterative procedures are required to compute the estimates. It can be shown that the REML estimator of h^2 is

$$\hat{h}_{\text{REML}}^2 = \frac{\sum_{i=1}^d a_i(h^2, \lambda_i, r_i) Q_i}{\sum_{i=1}^d b_i(h^2, \lambda_i, r_i) Q_i} \quad (18)$$

where a_i and b_i are functions of h^2 , λ_i , and r_i that serve as coefficients of Q_i . In essence, the REML estimator of h^2 is a ratio of linear combinations of the quadratic forms $Q_1, \dots, Q_d$ whose coefficients depend in part on the unknown parameter. The value of $\hat{h}_{\text{REML}}^2$ must be obtained iteratively by selecting a starting value and relying on the convergence of the procedure. See Refs. [7,10,11] for general information about ML estimation procedures.

INTERVAL ESTIMATION

Confidence intervals for variance components and for h^2 in particular are not typically symmetric. That is, the point estimate of h^2 does not necessarily lie at the center of the interval. Intervals are obtained by inverting a quantity that is a function of the responses and h^2 whose distribution is independent of h^2 . Specifically, if $\mathbf{Y}$ is multivariate normally distributed, then the elements of $\mathbf{Q}$ are chi-squared distributed and are independent as discussed in the subsection "Analysis of Variance Estimation." Because the ratio of independently chi-squared variates give rise to F -distributed quantities, it follows that a $100(1 - \alpha)\%$ confidence interval for h^2 can be computed by recognizing that

$$P \left(F_{\alpha_1} \leq \frac{\sum_{i=k+1}^d \frac{Q_i}{1 + h^2(\lambda_i - 1)} / \sum_{i=k+1}^d r_i}{\sum_{i=1}^k \frac{Q_i}{1 + h^2(\lambda_i - 1)} / \sum_{i=1}^k r_i} \leq F_{\alpha_2} \right) = 1 - \alpha \quad (19)$$

where $\alpha_1 + \alpha_2 = \alpha$ and F_{α_1} , F_{α_2} represent the α_1 and α_2 percentiles of the F -distribution having numerator and

denominator degrees of freedom equal to $\sum_{i=k+1}^d r_i$ and $\sum_{i=1}^k r_i$, respectively. By rewriting the joint inequality in the probability statement in Eq. 19 so that h^2 alone appears in the center, one can obtain a confidence interval for h^2 . If $d > 2$, this can only be accomplished using numerical techniques as no closed-form expression for the endpoints of the confidence interval exists. As previous discussions suggested, the choice of k is up to the investigator. Additional details are presented in Ref. [12].

HYPOTHESIS TESTS

Hypothesis tests for h^2 are useful if the investigator wants to determine if the sample information is consistent with a specific value of heritability under study. The hypothesis test developed in Ref. [9] is equivalent to the confidence interval given in the section “Interval Estimation.” To conduct the hypothesis test $H_0: h^2 = h_o^2$ vs. the two-sided hypothesis $H_1: h^2 \neq h_o^2$, define the test statistic to be

$$F^* = \frac{\sum_{i=k+1}^d \frac{Q_i}{1+h_o^2(\lambda_i-1)}}{\sum_{i=1}^k \frac{Q_i}{1+h_o^2(\lambda_i-1)}} \bigg/ \frac{\sum_{i=k+1}^d r_i}{\sum_{i=1}^k r_i} \quad (20)$$

Under H_0 , F^* is F -distributed with numerator and denominator degrees of freedom equal to $\sum_{i=k+1}^d r_i$ and $\sum_{i=1}^k r_i$, respectively. For a prespecified value of α , the type I error probability, reject H_0 if $F^* < F_{\alpha/2}$ or $F^* > F_{\alpha/2}$ and do not reject H_0 if $F_{\alpha/2} \leq F^* \leq F_{\alpha/2}$. One-sided tests may also be conducted using a similar procedure.

The locally most powerful (LMP) test has the property of being more powerful than any other test for values of h^2 that are close to h_o^2 . By definition, the LMP test is a test whose power function has maximum slope at $h^2 = h_o^2$. The test statistic for the LMP test is

$$T_{\text{LMP}} = \frac{(1-h_o^2) \sum_{i=1}^d \frac{\lambda_i Q_i}{(1+h_o^2(\lambda_i-1))^2}}{\sum_{i=1}^d \frac{Q_i}{1+h_o^2(\lambda_i-1)}} \quad (21)$$

Recall that $Q_i \sim (\sigma_e^2 + \lambda_i \sigma_1^2) \chi^2(r_i)$ are independent for $i = 1, \dots, d$. Under H_0 , the distribution of the test statistic is

$$\frac{(1-h_o^2) \sum_{i=1}^d \frac{\lambda_i \chi^2(r_i)}{1+h_o^2(\lambda_i-1)}}{\sum_{i=1}^d \chi^2(r_i)} \quad (22)$$

where the chi-squared random variables are independent. This testing procedure is discussed in some detail

in Ref. [13]. Neyman–Pearson tests and alternative testing procedures are given in Ref. [14].

DISCUSSION

In the preceding analyses, the investigator may be faced with the task of splitting the information contained in the quadratic forms $Q_1, \dots, Q_d$ into two separate pieces, namely $Q_1, \dots, Q_k$ and $Q_{k+1}, \dots, Q_d$. This becomes apparent by examining the ANOVA estimator of h^2 in Eq. 17, the confidence interval for h^2 as determined by Eq. 19, and the test statistic for h^2 in Eq. 20. The choice of k is simplified if $\lambda_1 = 0$. In this case, it is recommended that $k = 1$ so that Q_1 is separated from the remaining quadratic forms. See Table 1 for an example of this application. The choice of $k = 1$ corresponds to the Wald method in Ref. [15] for the unbalanced one-way random effects model. See Ref. [12] for guidance on how to select the value of k when $\lambda_1 > 0$.

The ML procedures are popular methods used to estimate variance components. Many statistical software packages will compute ML estimates of σ_1^2 , σ_2^2 and hence, h^2 , with very little effort required on the part of the investigator. These methods are based on iterative procedures that require initial estimates and employ well-designed algorithms to arrive at the solutions. While these procedures perform admirably in a wide variety of applications, there is no guarantee that the methods will always converge to a solution. Closed-form approximations to the REML estimator of h^2 are discussed in Ref. [16].

CONCLUSION

Other statistical procedures may be used to analyze heritability. Bootstrap and jackknife approaches may be useful. An overview of bootstrap estimates and bootstrap confidence intervals for variance components may be found in Ref. [17]. The analysis of heritability using Bayesian procedures may also be performed. In Ref. [7], the authors note that, because the REML estimation of variance components is based on a specific marginal likelihood function, it is equivalent to Bayesian estimation using noninformative priors.

Analysis of Variance (ANOVA)

Maria Overbeck-Larisch and Werner Sanns

University of Applied Sciences, Darmstadt, Germany

Abstract

The classical idea of the analysis of variance was to find out if there exists an influence of one or more categorical variables over a normally distributed random variable. This entry addresses this classical use of ANOVA as well as the modern approach which includes quantitative analysis by providing several sample analyses.

INTRODUCTION

The analysis of variance (ANOVA) is a statistical method, which originally was developed by R.A. Fisher (1890–1962) for problems in biological studies.^[2] Since that time, the ANOVA has been used in many different areas and there exist a comprehensive literature concerning the theory and practice of ANOVA.^[4,5,7–10] The classical idea of the ANOVA was to find out if there exists an influence of one or more categorical variables (factor variables) over a normally distributed random variable. This classical task of ANOVA can be regarded as a qualitative analysis. The modern approach to ANOVA, however, includes a quantitative analysis, too, via the general linear model (GLM) (i.e., it allows to measure the strength of the influence of each factor variable).

Practicing the ANOVA requires an appropriate software system. SAS® is one of these systems; it is a well-known tool in biopharmaceutical statistics. Therefore we include in this contribution the basic commands of the SAS procedures ANOVA and GLM (Ref. [6]).

MATHEMATICAL PROBLEM

Assume k random variables to be independent and normally distributed with the same variance σ^2 but with eventually different mean values (expected values) $\mu_1, \mu_2, \dots, \mu_k$. The objective of the ANOVA is to test the hypothesis H_0 of all mean values being equal against the alternative H_1 , which states that there are at least two different mean values. Thus the ANOVA is a statistical test procedure which, for $k = 2$, corresponds to the situation of the two-sample t -test. If the hypothesis holds, the k random variables have identical normal distributions. Otherwise, they have different mean values.

EXAMPLE 1 OF TOTAL PROTEIN IN SERUM

In toxicological studies, many parameters such as the number of red and white blood corpuscles (erythrocytes

and leucocytes) or the Na concentration in urine play an important role, and it is of great interest to know the statistical distribution of these parameters. Some of them such as the parameter TPRO (Total **PRO**tein in serum) can be assumed to be normally distributed. The following table contains the values of the parameter TPRO, where the measurements come from three control groups (not treated with the test compound) consisting of dogs, mice, and rats.

	Sex = f						Sex = m					
Species = Dog	5.7	5.4	5.8	5.5	5.1	5.5	5.5	5.4	5.4	5.0	5.4	5.9
Species = Mouse	5.9	5.4	5.7	5.4	5.3	5.9	6.1	5.4	6.1	5.8	5.6	6.3
Species = Rat	6.7	6.7	6.6	6.6	6.6	6.4	6.9	6.9	7.0	6.5	6.4	6.5

For further computations, we save the data set as a SAS file named TPRO with the three variables Species, Sex, and Value. In submitting the following SAS command lines, the file is created and printed on the screen in the output window:

```
data TPRO;

input Species$ Sex$ Value;

cards;

Dog f 5.7

Dog f 5.4

...

Dog m 5.9

Mouse f 5.9

...

Rat m 6.5

run;

proc print; run;
```

By means of a one-way ANOVA, we shall show that the values of the parameter TPRO differ significantly from species to species. One-way ANOVA means that the influence of only one factor, for instance the factor species, is taken into account.

But if one also takes into account the fact that the first six animals of each species are female whereas the last six animals are male, one may wonder if the factor Sex significantly influences the value of the parameter TPRO, too. By means of a two-way ANOVA, we will answer this question.

MODEL ASSUMPTIONS FOR THE ONE-WAY ANALYSIS OF VARIANCE

In the general situation of a one-way ANOVA, there are n observations in k different samples (because of the k levels of one categorical factor variable) of eventually different sample sizes $n_1, n_2, \dots, n_k$:

Sample 1	$y_{11}, y_{12}, \dots, y_{1n_1}$
Sample 2	$y_{21}, y_{22}, \dots, y_{2n_2}$
...	...
...	...
Sample k	$y_{k1}, y_{k2}, \dots, y_{kn_k}$

The observations y_{ij} , $1 \leq i \leq k$, and $1 \leq j \leq n_i$ come from random variables:

$$Y_{ij} = \mu_i + E_{ij} = \mu + \alpha_i + E_{ij}$$

where the E_{ij} variables are independent $N(0, \sigma^2)$ -distributed random variables. $\mu := (1/n) \sum_{i=1}^k 1\mu_i$ denotes the overall mean, and the parameters $\alpha_i : \mu_i - \mu$ denote the deviations of the particular mean values from μ . Because of this definition, the parameters α_i satisfy the condition:

$$\sum_{i=1}^k \alpha_i = 0$$

which later on could be used for recoding the parameters within the frame of the linear model. In terms of the parameter α_i , we have to test the hypothesis H_0 of all α_i being zero against the alternative H_1 that at least one $\alpha_i \neq 0$.

NOTATIONS

Some of the following notations are well known from other statistical methods:

$$n = \sum_{i=1}^k n_i$$

$$\bar{y}_i = \frac{1}{n_i} \sum_{j=1}^{n_i} y_{ij} \quad \text{and} \quad s_i^2 = \frac{1}{n_i - 1} \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2$$

$$\text{for } 1 \leq i \leq k$$

$$\bar{y} = \frac{1}{n} \sum_{i=1}^k \sum_{j=1}^{n_i} y_{ij} = \frac{1}{n} \sum_{i=1}^k n_i \bar{y}_i \quad \text{and} \quad s^2 = \frac{1}{n-1} \sum_{i=1}^k \sum_{j=1}^{n_i} (y_{ij} - \bar{y})^2$$

$$\text{sst} = \sum_{i=1}^k \sum_{j=1}^{n_i} (y_{ij} - \bar{y})^2 = (n-1)s^2$$

$$\text{ss1} = \sum_{i=1}^k n_i (\bar{y}_i - \bar{y})^2$$

$$\text{ss2} = \sum_{i=1}^k \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2 = \sum_{i=1}^k (n_i - 1) s_i^2$$

The name *analysis of variance* comes from the equation:

$$\text{sst} = \text{ss1} + \text{ss2}$$

which is valid as the following computation shows:

$$\begin{aligned} \text{sst} &= \sum_{i=1}^k \sum_{j=1}^{n_i} (y_{ij} - \bar{y})^2 \\ &= \sum_{i=1}^k \sum_{j=1}^{n_i} \left((y_{ij} - \bar{y}_i) + (\bar{y}_i - \bar{y}) \right)^2 \\ &= \sum_{i=1}^k \sum_{j=1}^{n_i} \left((y_{ij} - \bar{y}_i)^2 + (\bar{y}_i - \bar{y})^2 + 2(y_{ij} - \bar{y}_i)(\bar{y}_i - \bar{y}) \right) \\ &= \sum_{i=1}^k \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2 + 2 \sum_{i=1}^k (\bar{y}_i - \bar{y}) \underbrace{\sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)}_{=0} \\ &\quad + \sum_{i=1}^k \sum_{j=1}^{n_i} (\bar{y}_i - \bar{y})^2 = \text{ss2} + \text{ss1} \end{aligned}$$

Interpretation: The total sum of square (sst) (i.e., the sum over all squared differences between the total mean and the particular observation) can be split into two sums ss1 and ss2. The first one is a result of the differences *between* the samples, and the second one is a result of the differences *within* the samples. So the above equation can be written in the form:

$$\text{sst} = \text{ss1} + \text{ss2} = \text{ss}_{\text{between}} + \text{ss}_{\text{within}}$$

It seems to be reasonable to reject the hypothesis that the k normal distributions are identical if the quotient $\text{ss}_{\text{between}} / \text{ss}_{\text{within}}$ is large. The question how large the quotient has to be in order to reject the hypothesis can be answered by the following theorem.

THEOREM

If the model assumptions are fulfilled and if the hypothesis of equal means is true, we can state the following:

$$\frac{sst}{\sigma^2} = \frac{1}{\sigma^2} \sum_{i=1}^k \sum_{j=1}^{n_i} (Y_{ij} - \bar{Y})^2 \sim \chi_{n-1}^2$$

$$\frac{ss1}{\sigma^2} = \frac{1}{\sigma^2} \sum_{i=1}^k n_i (\bar{Y}_i - \bar{Y})^2 \sim \chi_{k-1}^2$$

$$\frac{ss2}{\sigma^2} = \frac{1}{\sigma^2} \sum_{i=1}^k \sum_{j=1}^{n_i} (Y_{ij} - \bar{Y}_i)^2 \sim \chi_{n-k}^2$$

$$V := \frac{ss1 / (k-1)}{ss2 / (n-k)} \sim F_{k-1, n-k}$$

Under H_0 , the random variable V assumes small values. Thus H_0 can be rejected if the realized value v of the test variable V exceeds a critical value v^* . For a given significance level α , the critical value v^* is determined in such a way that:

$$P(V > v^* | H_0) = \alpha$$

Let F be the cumulative distribution function of the $F_{k-1, n-k}$ distribution. Then the critical value v^* is the solution of the equation:

$$1 - F(v^*) = \alpha$$

or

$$v^* = F^{-1}(1 - \alpha)$$

respectively. This means that v^* is the $(1 - \alpha)$ percentile of the $F_{k-1, n-k}$ distribution.

Therefore we have the following procedure for a one-way ANOVA:

1st step: Choose an appropriate significance level α .

2nd step: Compute the $(1 - \alpha)$ percentile of the $F_{k-1, n-k}$ distribution.

3rd step: Compute $\bar{y}_1, \dots, \bar{y}_k, \bar{y}, s_1^2, \dots, s_k^2, ss1, ss2$, and $v = [ss1/(k-1)]/[ss2/(n-k)]$.

4th step: Reject H_0 if $v > v^*$.

REMARK

It is obvious that the above theorem and the resulting procedure for a one-way ANOVA strongly depend on the assumption of normally distributed random variable Y_{ij} . If this condition is not satisfied, the test variables V is not appropriate and a distribution-free test like the test of Kruskal–Wallis should be chosen.

EXAMPLE 2 OF TOTAL PROTEIN IN SERUM

As the TPRO value can be assumed to be normally distributed, we follow the given procedure for a one-way ANOVA ($k = 3, n = 36$):

1st step: If the aim is to show that the values of the parameter TPRO differ significantly from species to species, we choose a small significance level. We choose the standard level of 5%.

2nd step: We have to compute the 95% percentile of the $F_{2,33}$ distribution. This can be performed, for instance, by the following SAS program:

```
data temp;
vstar=Finv(0.95,2,33); run;
proc print; run;
```

We get $v^* = 3.28492$.

3rd step: Submitting the SAS commands:

```
proc means data=TPRO; run;
proc means data=TPRO; by Species; run;
```

the following results can be achieved:

$\bar{y} = 5.9527778$	$\bar{y}_1 = 5.4666667$	$\bar{y}_2 = 5.7416667$	$\bar{y}_3 = 6.6500000$
$s = 0.5744494$	$s_1 = 0.2570226$	$s_2 = 0.3287949$	$s_3 = 0.1977142$

So we have:

$$ss1 = \sum_{i=1}^k n_i (\bar{y}_i - \bar{y})^2 = 12 \sum_{i=1}^3 (\bar{y}_i - \bar{y})^2 = 9.20388889$$

$$ss2 = \sum_{i=1}^k (n_i - 1) s_i^2 = 11 \sum_{i=1}^3 s_i^2 = 2.34583333$$

$$v = \frac{ss1 / (k-1)}{ss2 / (n-k)} = \frac{9.20388889 / 2}{2.34583333 / 33} = 64.738$$

4th step: As $v > v^*$, the hypothesis H_0 can be rejected at the 5% significance level. The means of the three species differ significantly.

These and a lot of more computational results can be achieved by putting the SAS procedure ANOVA into action. The SAS program:

```
proc anova data=TPRO;
class Species;
model Value=Species;
run;
```

yields, among other results, the ANOVA table at the base of this page (we added our symbols in parentheses).

There are two more or less remarkable differences between our handmade calculation and the SAS output. The first one concerns the notation: The sum $ss1 = ss_{\text{between}}$ describes that part of the total sum of squares that corresponds to the model, whereas the sum $ss2 = ss_{\text{within}}$ is the remaining error sum of squares. For a better understanding of the SAS output, denote $ss1$ by ss_{model} and denote $ss2$ by ss_{error} and write the equation of a one-way ANOVA in the form:

$$sst = ss_{\text{model}} + ss_{\text{error}}$$

The second difference is more essential: SAS does not compute the 95% percentile v^* of the $F_{2,33}$ distribution, but in the column with the title “ $Pr > F$ ” it produces the probability $1 - F(v)$ or an upper bound. Here this upper bound is 0.0001. Because of the equivalence:

$$v > v^* \quad F(v) > F(v^*) \quad F(v) > 1 - \alpha \quad 1 - F(v) < \alpha$$

the hypothesis can be rejected as long as the value $1 - F(v)$ is less than the chosen significance level α . As already mentioned, SAS produces some more computational results that are not printed above. As a very important number, for instance, we get:

$$R^2 = ss1 / sst = ss_{\text{between}} / ss_{\text{total}} = ss_{\text{model}} / ss_{\text{total}}$$

which tells us how much of the total sum of squares can be explained by the model. In the example of TPRO, $R^2 = 0.796893$ means that about 80% of the variation in the data set can be explained by the fact that the animals belong to different species.

MODEL ASSUMPTIONS FOR THE TWO-WAY ANALYSIS OF VARIANCE

Within the framework of a two-way ANOVA or a higher-way ANOVA, we simultaneously explore if there is an influence of two or more categorical variables (factor variables) over a normally distributed random variable. For the sake of simplicity, let us restrict ourselves to a situation with only two factor variables. Regarding our TPRO data set, we want to find out simultaneously if the Species or the Sex has an effect on the value of the parameter TPRO. The two factor variables divide the observations in r rows and p columns with $r \times p$ cells (samples). Assume, furthermore, that there are m observations in each cell: So for the number n of observations, we have $n = rpm$. (In case of $m = 1$, we have the situation of a simple block experiment.)

Let us assume the observations y_{ijl} , $1 \leq i \leq r$, $1 \leq j \leq p$, and $1 \leq l \leq m$ to come from random variables:

$$Y_{ijl} = \mu + \alpha_i + \beta_j + E_{ijl}$$

with independent $N(0, \sigma^2)$ -distributed random variables E_{ijl} . α_i denotes the effect of the i th row and β_j denotes the effect of the j th column. As in the model of a one-way ANOVA, we assume two reparameterization conditions to be valid:

$$\sum_{i=1}^r \alpha_i = 0 \quad \text{and} \quad \sum_{j=1}^p \beta_j = 0$$

So we have to test the hypothesis $H_0: \alpha_1 = \dots = \alpha_r = \beta_1 = \dots = \beta_p = 0$ against the alternative H_1 that at least one of these $r + p$ parameters does not have a value of zero.

Class Level Information					
Class		Levels	Values		
Species		3	Dog	Mouse	Rat
Number of observations				36	
The ANOVA Procedure					
Dependent Variable: Value					
Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	2 ($k-1$)	9.20388889 (ss1)	4.60194444 ($ss1/(k-1)$)	64.74 (v)	<.0001
Error	33 ($n-k$)	2.34583333 (ss2)	0.07108586 ($ss2/(n-k)$)		
Corrected Total	35 ($n-1$)	11.54972222 (sst)			

NOTATIONS

$$\bar{y} = \frac{1}{rpm} \sum_{i=1}^r \sum_{j=1}^p \sum_{l=1}^m y_{ijl} \quad sst = \sum_{i=1}^r \sum_{j=1}^p \sum_{l=1}^m (y_{ijl} - \bar{y})^2$$

$$\bar{y}_{i..} = \frac{1}{pm} \sum_{j=1}^p \sum_{l=1}^m y_{ijl} \quad ss1 = \sum_{i=1}^r pm(\bar{y}_{i..} - \bar{y})^2$$

for $1 \leq i \leq r$

$$\bar{y}_{.j.} = \frac{1}{rm} \sum_{i=1}^r \sum_{l=1}^m y_{ijl} \quad ss2 = \sum_{j=1}^p rm(\bar{y}_{.j.} - \bar{y})^2$$

for $1 \leq j \leq p$

$$ss3 = \sum_{i=1}^r \sum_{j=1}^p \sum_{l=1}^m (y_{ijl} - \bar{y}_{i..} - \bar{y}_{.j.} + \bar{y})^2$$

As in the case of a one-way ANOVA, the basic idea is to split the total sum of squares:

$$sst = ss1 + ss2 + ss3$$

Here $ss1$ is a result of the differences between the rows, $ss2$ is a result of the differences between the columns, and $ss3$ is the remaining error sum of squares. If the model assumptions are fulfilled and if the hypothesis is true, we can state: The random variables $ss1/\sigma^2$, $ss2/\sigma^2$, and $ss3/\sigma^2$ are χ^2 -distributed. The number of degrees of freedom of $ss1/\sigma^2$ and $ss2/\sigma^2$ is $r-1$ and $p-1$, respectively. The number of degrees of freedom of $ss3/\sigma^2$ is $n-1-(r-1)-(p-1) = n+1-r-p$ with $n = rpm$. Furthermore, we have:

$$V_1 : \frac{ss1/(r-1)}{ss3/(n+1-r-p)} \sim F_{(r-1), (n+1-r-p)}$$

$$V_2 : \frac{ss2/(p-1)}{ss3/(n+1-r-p)} \sim F_{(p-1), (n+1-r-p)}$$

The hypothesis H_0 can be rejected if the realization v_1 of the test variable V_1 is greater than the $(1-\alpha)$ percentile v_1^* of the F -ratio distribution with $(r-1), (n+1-r-p)$ degrees of freedom, or if the realized value v_2 of the test variable V_2 is greater than the $(1-\alpha)$ percentile v_2^* of the F -ratio distribution with $(p-1), (n+1-r-p)$ degrees of freedom. This rejection rule is equivalent to the demands:

$$P(V_1 > v_1 | H_0) = 1 - F_1(v_1) < \alpha \quad \text{or}$$

$$P(V_2 > v_2 | H_0) = 1 - F_2(v_2) < \alpha$$

Here the functions F_1 and F_2 are the cumulative distribution functions of the F -ratio distributions with $(r-1), (n+1-r-p)$ and $(p-1), (n+1-r-p)$ degrees of freedom, respectively.

	Column			
	1	2	...	P
1	$y_{111}, y_{112}, \dots, y_{11m}$	$y_{121}, \dots, y_{12m}$	...	$y_{1p1}, \dots, y_{1pm}$
Row 2	$y_{211}, y_{212}, \dots, y_{21m}$	$y_{221}, \dots, y_{22m}$	...	$y_{2p1}, \dots, y_{2pm}$
3	$y_{311}, y_{312}, \dots, y_{31m}$	$y_{321}, \dots, y_{32m}$	...	$y_{3p1}, \dots, y_{3pm}$
...	...	...	...	...
r	$y_{r11}, y_{r12}, \dots, y_{r1m}$	$y_{r21}, \dots, y_{r2m}$	...	$y_{rp1}, \dots, y_{rpm}$

EXAMPLE 3 OF TOTAL PROTEIN IN SERUM

Submitting the SAS program:

```
proc anova data=TPRO;
    class Species Sex;
    model Value=Species Sex;
run;
```

one gets the ANOVA table at the base of this page.

As $1 - F_1(v_1) = 1 - F_1(65.58) < 0.0001 < \alpha = 5\%$, the hypothesis of no differences between the Species can be rejected. But as $1 - F_2(v_2) = 1 - F_2(1.43) = 0.2407$ is much greater than the significance level of $\alpha = 5\%$, the hypothesis of no differences between the Sex cannot be rejected.

Note that the R^2 is nearly the same as in the model with the one factor variable, Species.

If the number m of observations in the single cells is greater than one, the model of a two-way ANOVA allows one to include interactions. The corresponding model equations are:

$$y_{ijl} = \mu + \alpha_i + \beta_j + (\alpha\beta)_{ij} + E_{ijl}$$

where the following equations are assumed to be true:

$$\sum_{i=1}^r \alpha_i = 0, \quad \sum_{j=1}^p \beta_j = 0$$

$$\sum_{i=1}^r (\alpha\beta)_{ij} = 0 \text{ for all } 1 \leq i \leq r;$$

$$\sum_{i=1}^r (\alpha\beta)_{ij} = 0 \text{ for all } 1 \leq j \leq p$$

Without discussing this model in detail, we submit the following SAS program:

```
proc anova data=TPRO;
    class Species Sex;
    model Value=Species Sex Species*Sex;
run;
```

The SAS output contains an additional line for the interactions between the categorical variables Species and Sex. As the computed probability $1 - F(v_3) = 0.2776$ is much greater than the assumed significance level of 5%, we conclude that there are no significant interactions.

LINEAR MODEL OF ANALYSIS OF VARIANCE

To begin with, assume the situation of a one-way ANOVA with $k = 3$ samples (such as in the example of TPRO, where the samples correspond to different species):

Class Level Information		
Class	Levels	Values
Species	3	Dog Mouse Rat
Sex	2	f m
Number of observations		36

The ANOVA Procedure					
Dependent Variable: Value					
Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	3	9.30416667	3.10138889	44.20	<.0001
Error	32	2.24555556	0.07017361		
Corrected Total	35	11.54972222			
	R-Square	Coeff Var	Root MSE	Value Mean	
	0.805575	4.450074	0.264903	5.952778	
Source	DF	Anova SS	Mean Square	F Value	Pr > F
Species	2	9.20388889	4.60194444	65.58	<.0001
Sex	1	0.10027778	0.10027778	1.43	0.2407

Sample 1	$y_{11}, y_{12}, \dots, y_{1n_1}$
Sample 2	$y_{21}, y_{22}, \dots, y_{2n_2}$
Sample 3	$y_{31}, y_{32}, \dots, y_{3n_3}$

The n model equation is:

$$Y_{ij} = \mu_i + E_{ij} = \mu + \alpha_i + E_{ij} \quad \text{for } i = 1, 2, 3 \text{ and } 1 \leq j \leq n_i$$

Apply the following transformation to the observed value y_{ij} and to the corresponding random variables Y_{ij} and E_{ij} :

$$\mathbf{y} = \begin{pmatrix} y_{11} \\ y_{12} \\ \dots \\ y_{1n_1} \\ y_{21} \\ y_{22} \\ \dots \\ y_{2n_2} \\ y_{31} \\ y_{32} \\ \dots \\ y_{3n_3} \end{pmatrix} = \begin{pmatrix} y_1 \\ y_2 \\ \dots \\ y_{n_1} \\ y_{n_1+1} \\ y_{n_1+2} \\ \dots \\ y_{n_1+n_2} \\ y_{n_1+n_2+1} \\ y_{n_1+n_2+2} \\ \dots \\ y_n \end{pmatrix}$$

$$\mathbf{Y} = \begin{pmatrix} Y_1 \\ Y_2 \\ \dots \\ Y_{n_1} \\ Y_{n_1+1} \\ Y_{n_1+2} \\ \dots \\ Y_{n_1+n_2} \\ Y_{n_1+n_2+1} \\ Y_{n_1+n_2+2} \\ \dots \\ Y_n \end{pmatrix} \quad \mathbf{E} = \begin{pmatrix} E_1 \\ E_2 \\ \dots \\ E_{n_1} \\ E_{n_1+1} \\ E_{n_1+2} \\ \dots \\ E_{n_1+n_2} \\ E_{n_1+n_2+1} \\ E_{n_1+n_2+2} \\ \dots \\ E_n \end{pmatrix}$$

Now the n model equations can be rewritten in the form:

$$Y_i = \mu x_{i0} + \alpha_1 x_{i1} + \alpha_2 x_{i2} + \alpha_3 x_{i3} + E_i$$

where

$$x_{i0} = 1 \quad \text{for all } 1 \leq i \leq n$$

$$x_{i1} = \begin{cases} 1 & \text{if } 1 \leq i \leq n_1 \\ 0 & \text{else} \end{cases}$$

$$x_{i2} = \begin{cases} 1 & \text{if } n_1 + 1 \leq i \leq n_1 + n_2 \\ 0 & \text{else} \end{cases}$$

$$x_{i3} = \begin{cases} 1 & \text{if } n_1 + n_2 + 1 \leq i \leq n \\ 0 & \text{else} \end{cases}$$

Then we have:

$$\mathbf{Y} = \begin{pmatrix} Y_1 \\ Y_2 \\ \dots \\ Y_{n_1} \\ Y_{n_1+1} \\ Y_{n_1+2} \\ \dots \\ Y_{n_1+n_2} \\ Y_{n_1+n_2+1} \\ Y_{n_1+n_2+2} \\ \dots \\ Y_n \end{pmatrix} = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ \dots & \dots & \dots & \dots \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 1 & 0 \\ \dots & \dots & \dots & \dots \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ \dots & \dots & \dots & \dots \\ 1 & 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} \mu \\ \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{pmatrix}$$

$$+ \mathbf{E} = \mathbf{X} \cdot \boldsymbol{\beta} + \mathbf{E}; \quad \boldsymbol{\beta} = \begin{pmatrix} \mu \\ \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{pmatrix}$$

The equation:

$$\mathbf{Y} = \mathbf{X} \cdot \boldsymbol{\beta} + \mathbf{E}; \quad \mathbf{X} = (x_{ij})_{1 \leq i \leq n, 0 \leq j \leq 3}$$

is similar to a linear intercept regression model with $k = 3$ factor variables (called regressors). But there is the following important difference concerning the elements of the design matrix $\mathbf{X}$: When $\mathbf{X}$ is the design matrix of a linear intercept regression model, for $j \geq 1$, the element x_{ij} is the i th adjusted value for the j th regressor. In the present linear model of a one-way ANOVA, the element x_{ij} of the design matrix $\mathbf{X}$ is an element of the set $\{0,1\}$. For $j \geq 1$, the value x_{ij} only denotes which sample the i th observation belongs to.

For generalizing the one-way model, assume that the number of samples is an arbitrary number $k \geq 2$. In the general case, the design matrix $\mathbf{X}$ has n rows and $k + 1$ columns. All elements of the first column have a value of 1. In the second column, we have n_1 leading elements with a value of 1, followed by $n - n_1$ zeros. In the 3rd column, we have n_1 leading zeros, followed by n_2 elements with a value of 1 and further $n - n_1 - n_2$ zeros. The last column begins with $n - n_k$ zeros, followed by n_k ones. So we have:

$$\mathbf{X} = \begin{pmatrix} \mathbf{1}_{n_1} & \mathbf{1}_{n_1} & \mathbf{0}_{n_1} & \mathbf{0}_{n_1} & \mathbf{0}_{n_1} & \dots & \mathbf{0}_{n_1} \\ \mathbf{1}_{n_2} & \mathbf{0}_{n_2} & \mathbf{1}_{n_2} & \mathbf{0}_{n_2} & \mathbf{0}_{n_2} & \dots & \mathbf{0}_{n_2} \\ \mathbf{1}_{n_3} & \mathbf{0}_{n_3} & \mathbf{0}_{n_3} & \mathbf{1}_{n_3} & \mathbf{0}_{n_3} & \dots & \mathbf{0}_{n_3} \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ \mathbf{1}_{n_k} & \mathbf{0}_{n_k} & \mathbf{0}_{n_k} & \mathbf{0}_{n_k} & \mathbf{0}_{n_k} & \dots & \mathbf{1}_{n_k} \end{pmatrix}, \quad \boldsymbol{\beta} = \begin{pmatrix} \mu \\ \alpha_1 \\ \alpha_2 \\ \dots \\ \alpha_k \end{pmatrix}$$

Here $\mathbf{1}_{n_j}$ denotes the n_j -dimensional column vector with all its components having a value of 1 and $\mathbf{0}_{n_j}$ is the n_j -dimensional zero vector.

EXAMPLE 4 OF TOTAL PROTEIN IN SERUM

Neglecting the influence of the factor variable Sex, we have a one-way ANOVA with the linear model equation:

$$\mathbf{Y} = \begin{pmatrix} Y_1 \\ \dots \\ Y_{12} \\ Y_{13} \\ \dots \\ Y_{24} \\ Y_{25} \\ \dots \\ Y_{36} \end{pmatrix} = \begin{pmatrix} \mathbf{1}_{12} & \mathbf{1}_{12} & \mathbf{0}_{12} & \mathbf{0}_{12} \\ \mathbf{1}_{12} & \mathbf{0}_{12} & \mathbf{1}_{12} & \mathbf{0}_{12} \\ \mathbf{1}_{12} & \mathbf{0}_{12} & \mathbf{0}_{12} & \mathbf{1}_{12} \end{pmatrix} \cdot \begin{pmatrix} \mu \\ \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{pmatrix}$$

$$+ \mathbf{E} = \mathbf{X} \cdot \boldsymbol{\beta} + \mathbf{E}; \quad \boldsymbol{\beta} = \begin{pmatrix} \mu \\ \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{pmatrix}$$

The equations for the linear model of a two-way ANOVA with $r \times p$ samples are:

$$Y_i = \mu x_{i0} + \alpha_1 x_{i1} + \alpha_2 x_{i2} + \dots + \alpha_r x_{ir} + \beta_1 x_{i(r+1)} + \dots + \beta_p x_{i(r+p)} + E_i$$

Here for all $1 \leq i \leq n$, the coefficient x_{i0} of the parameter μ has a value of 1. For $1 \leq j \leq r$, the coefficient x_{ij} of the

parameter α_j has a value of 1, if the observation with number i belongs to the j th category of the first factor variable; else x_{ij} has a value of 0. For $1 \leq j \leq p$, the coefficient $x_{i(r+j)}$ of the parameter β_j has a value of 1, if the observation with number i belongs to the j th category of the second factor variable. Otherwise, $x_{i(r+j)}$ has a value of 0.

EXAMPLE 5 OF TOTAL PROTEIN IN SERUM

Taking into account the fact that the first six observations for each species are female whereas the last six observations are male animals, we write the model in the following way ($r = 3, p = 2$):

$$Y_i = \mu x_{i0} + \alpha_1 x_{i1} + \alpha_2 x_{i2} + \alpha_3 x_{i3} + \beta_1 x_{i4} + \beta_2 x_{i5} + E_i$$

Here the numbers x_{i0} , x_{i1} , x_{i2} , and x_{i3} are defined as above in the linear model of one-way ANOVA, whereas the additional numbers x_{i4} and x_{i5} characterize the sex of the animals. Formally, they are defined in the following way:

$$x_{i4} = \begin{cases} 1 & \text{if the } i\text{th observation comes from a female} \\ 0 & \text{animal else} \end{cases}$$

$$x_{i5} = \begin{cases} 1 & \text{if the } i\text{th observation comes from a male animal} \\ 0 & \text{else} \end{cases}$$

So we get the linear model for the two-way ANOVA:

$$\mathbf{Y} = \begin{pmatrix} Y_1 \\ \dots \\ Y_{12} \\ Y_{13} \\ \dots \\ Y_{24} \\ Y_{25} \\ \dots \\ Y_{36} \end{pmatrix} = \begin{pmatrix} \mathbf{1}_6 & \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{0}_6 & \mathbf{1}_6 & \mathbf{0}_6 \\ \mathbf{1}_6 & \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{0}_6 & \mathbf{0}_6 & \mathbf{1}_6 \\ \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{1}_6 & \mathbf{0}_6 \\ \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{0}_6 & \mathbf{1}_6 \\ \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{0}_6 & \mathbf{1}_6 & \mathbf{1}_6 & \mathbf{0}_6 \\ \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{0}_6 & \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{1}_6 \end{pmatrix} \cdot \begin{pmatrix} \mu \\ \alpha_1 \\ \alpha_2 \\ \alpha_3 \\ \beta_1 \\ \beta_2 \end{pmatrix}$$

$$+ \mathbf{E} = \mathbf{X} \cdot \boldsymbol{\beta} + \mathbf{E}; \quad \boldsymbol{\beta} = \begin{pmatrix} \mu \\ \alpha_1 \\ \alpha_2 \\ \alpha_3 \\ \beta_1 \\ \beta_2 \end{pmatrix}$$

The aim of the classical ANOVA is to examine if all sample effects are 0. But as soon as one has formulated the

linear model $\mathbf{Y} = \mathbf{X} \cdot \boldsymbol{\beta} + \mathbf{E}$ of the ANOVA, one can do more than this *qualitative analysis* and ask the same questions as in regression analysis. Finding estimators for the parameters and testing the hypotheses on them is a *quantitative analysis*.

In regression analysis, the parameter vector $\boldsymbol{\beta}$ of the linear model $\mathbf{Y} = \mathbf{X} \cdot \boldsymbol{\beta} + \mathbf{E}$ is estimated by the least squares method (LSM). This means that the least squares estimator (LSE) $\mathbf{b}$ has to minimize the function:

$$f(\mathbf{b}) = (\mathbf{y} - \mathbf{X}\mathbf{b})^T (\mathbf{y} - \mathbf{X}\mathbf{b})$$

Simple computations show that the function f becomes minimal if and only if $\mathbf{b}$ is the solution of the so-called normal equations:

$$(\mathbf{X}^T \mathbf{X}) \mathbf{b} = \mathbf{X}^T \mathbf{y}$$

If the matrix $\mathbf{X}$ has a full rank, the matrix $\mathbf{X}^T \mathbf{X}$ is regular and the unique solution of the system of normal equations is:

$$\mathbf{b} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}$$

It is important to emphasize that the LSE $\mathbf{b} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}$ is an unbiased estimator of the unknown parameter vector $\boldsymbol{\beta}$ of the linear model $\mathbf{Y} = \mathbf{X} \cdot \boldsymbol{\beta} + \mathbf{E}$ for every distribution of the random vector $\mathbf{E}$. Thus contrary to the classical approach to ANOVA, where we assume from the very beginning that $\mathbf{E}$ follows a normal distribution law, this assumption is not necessary for estimating the parameter vector $\boldsymbol{\beta}$ of the linear model by means of the LSM.

But there arises another problem: The design matrix $\mathbf{X}$ of the linear model for the one-way ANOVA does not have a full rank. If the factor variable divides the observations in k samples, the matrix $\mathbf{X}$ has $1 + k$ columns. The first column with elements $x_{i0} = 1, 1 \leq i \leq n$ is the sum of the following k columns. The problem is intensified if $\mathbf{X}$ is the design matrix of a linear model for two-way ANOVA. If the two factor variables divide the observations in $r \times p$ samples, the matrix $\mathbf{X}$ has $1 + r + p$ columns. The first column of $\mathbf{X}$ with elements $x_{i0} = 1, 1 \leq i \leq n$ is the sum of the following r columns and it is the sum of the last p columns as well. As a consequence, the matrix $\mathbf{X}^T \mathbf{X}$ is not regular and does not have an inverse.

EXAMPLE 6 OF TOTAL PROTEIN IN SERUM

Neglecting the influence of the factor variable Sex, the design matrix $\mathbf{X}$ of the linear model of this one-way ANOVA satisfies the equation:

$$\mathbf{X}^T \mathbf{X} = \begin{pmatrix} 36 & 12 & 12 & 12 \\ 12 & 12 & 0 & 0 \\ 12 & 0 & 12 & 0 \\ 12 & 0 & 0 & 12 \end{pmatrix}$$

This matrix is not regular: The first column is the sum of the last three columns. If the factor Sex, too, is taken into account, the design matrix $\mathbf{X}$ of the linear model of this two-way ANOVA satisfies the equation:

$$\mathbf{X}^T \mathbf{X} = \begin{pmatrix} 36 & 12 & 12 & 12 & 18 & 18 \\ 12 & 12 & 0 & 0 & 6 & 6 \\ 12 & 0 & 12 & 0 & 6 & 6 \\ 12 & 0 & 0 & 12 & 6 & 6 \\ 18 & 6 & 6 & 6 & 18 & 0 \\ 18 & 6 & 6 & 6 & 0 & 18 \end{pmatrix}$$

This matrix is not regular: The first column is the sum of the following three columns and it is the sum of the last two columns as well.

There are two methods for getting LSEs in this situation. The SAS procedure GLM uses a generalized inverse, which is defined in the following way: The (m,n) matrix $\mathbf{A}^-$ is a generalized inverse of the (n,m) matrix $\mathbf{A}$ if the equation:

$$\mathbf{A} \cdot \mathbf{A}^- \cdot \mathbf{A} = \mathbf{A}$$

is satisfied. If $\mathbf{A}$ is a regular quadratic matrix, it has exactly one generalized inverse and this is the inverse matrix $\mathbf{A}^{-1}$; else the generalized inverse of the matrix $\mathbf{A}$ is not unique. If the equation system $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$, where $\mathbf{A}$ is an (n,m) matrix and $\mathbf{b}$ is an n -dimensional vector, is solvable, the set of all solutions is:

$$\{\mathbf{x} \mid \mathbf{x} = \mathbf{A}^- \cdot \mathbf{b} + (\mathbf{A}^- \cdot \mathbf{A} - \mathbf{I}_m) \cdot \mathbf{z}, \mathbf{z} \in \mathbb{R}^m\}$$

So one special solution of the linear equation system $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$ is the vector $\mathbf{x} = \mathbf{A}^- \cdot \mathbf{b}$.

Applying this statement to the system $(\mathbf{X}^T \mathbf{X}) \cdot \mathbf{b} = \mathbf{X}^T \mathbf{y}$ of normal equations, we have the following: If $\mathbf{G}$ is a generalized inverse of the matrix $\mathbf{X}^T \mathbf{X}$, the vector $\mathbf{b} = \mathbf{G} \mathbf{X}^T \mathbf{y}$ is only a special solution, which, moreover, is not an unbiased estimator for the unknown parameter vector $\boldsymbol{\beta}$.

EXAMPLE 7 OF TOTAL PROTEIN IN SERUM

The appropriate SAS procedure is GLM. In submitting the commands:

```
proc glm data=TPRO;

class Species;

model Value=Species;

run;
```

the SAS generates the same output as when using the SAS procedure ANOVA for the one-way case. But extending

the model command line by the option solution makes SAS compute, in addition, a special solution $\mathbf{b}$ of the system of normal equations by means of a special generalized inverse $\mathbf{G}$ of the matrix $\mathbf{X}^T \mathbf{X}$. Extending the model command line once more by the two options xpx and i, the matrix $\mathbf{X}^T \mathbf{X}$ and the generalized inverse $\mathbf{G}$ are printed in the output window, too. Thus when submitting for the one-way ANOVA the SAS commands:

```
proc glm data=TPRO;

class Species;

model Value=Species/solution xpx i;

run;
```

the SAS computes:

$$\mathbf{X}^T \mathbf{X} = \begin{pmatrix} 36 & 12 & 12 & 12 \\ 12 & 12 & 0 & 0 \\ 12 & 0 & 12 & 0 \\ 12 & 0 & 0 & 12 \end{pmatrix}$$

$$\mathbf{G} = \begin{pmatrix} 0.083333333 & -0.083333333 & -0.083333333 & 0 \\ -0.083333333 & 0.166666667 & 0.083333333 & 0 \\ -0.083333333 & 0.083333333 & 0.166666667 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

$$\mathbf{b} = \begin{pmatrix} \hat{\mu} \\ \hat{\alpha}_1 \\ \hat{\alpha}_2 \\ \hat{\alpha}_3 \end{pmatrix} = \begin{pmatrix} 6.650000000 \\ -1.183333333 \\ -0.908333333 \\ 0.000000000 \end{pmatrix}$$

The output contains the note that the estimates for the intercept μ and for the three effects $\alpha_1, \alpha_2, \alpha_3$ of the three species Dog, Mouse, and Rat are biased and not unique.

The second method for solving the problem of a less-than-full-rank design matrix $\mathbf{X}$ requires a recoding of the parameters to be estimated, which implies a reduction of its number and another interpretation. In the case of a one-way ANOVA with k samples, we make use of the fact that for every i , the number x_{i0} equals 1 and the sum $x_{i1} + x_{i2} + \dots + x_{ik}$ has a value of 1, too. So the model can be rewritten in the following form:

$$\begin{aligned} Y_i &= \mu x_{i0} + \alpha_1 x_{i1} + \alpha_2 x_{i2} + \dots + \alpha_{k-1} x_{i(k-1)} + \alpha_k x_{ik} + E_i \\ &= \mu x_{i0} + \alpha_1 x_{i1} + \alpha_2 x_{i2} + \dots + \alpha_{k-1} x_{i(k-1)} + \alpha_k x_{ik} \\ &\quad + E_i + \alpha_k x_{i0} - \alpha_k (x_{i1} + x_{i2} + \dots + x_{ik}) \\ &= (\mu + \alpha_k) x_{i0} + (\alpha_1 - \alpha_k) x_{i1} + (\alpha_2 - \alpha_k) x_{i2} + \dots \\ &\quad + (\alpha_{k-1} - \alpha_k) x_{i(k-1)} + (\alpha_k - \alpha_k) x_{ik} + E_i \\ &= (\mu + \alpha_k) x_{i0} + (\alpha_1 - \alpha_k) x_{i1} + (\alpha_2 - \alpha_k) x_{i2} + \dots \\ &\quad + (\alpha_{k-1} - \alpha_k) x_{i(k-1)} + E_i \end{aligned}$$

The design matrix $\mathbf{X}$ of this linear model has k columns instead of $k + 1$ and the parameter vector β has k components instead of $k + 1$:

$$\mathbf{X} = \begin{pmatrix} \mathbf{1}_{n_1} & \mathbf{1}_{n_1} & \mathbf{0}_{n_1} & \mathbf{0}_{n_1} & \mathbf{0}_{n_1} & \dots & \mathbf{0}_{n_1} \\ \mathbf{1}_{n_2} & \mathbf{0}_{n_2} & \mathbf{1}_{n_2} & \mathbf{0}_{n_2} & \mathbf{0}_{n_2} & \dots & \mathbf{0}_{n_2} \\ \mathbf{1}_{n_3} & \mathbf{0}_{n_3} & \mathbf{0}_{n_3} & \mathbf{1}_{n_3} & \mathbf{0}_{n_3} & \dots & \mathbf{0}_{n_3} \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ \mathbf{1}_{n_{k-1}} & \mathbf{0}_{n_{k-1}} & \mathbf{0}_{n_{k-1}} & \mathbf{0}_{n_{k-1}} & \mathbf{0}_{n_{k-1}} & \dots & \mathbf{1}_{n_{k-1}} \\ \mathbf{1}_{n_k} & \mathbf{0}_{n_k} & \mathbf{0}_{n_k} & \mathbf{0}_{n_k} & \mathbf{0}_{n_k} & \dots & \mathbf{0}_{n_k} \end{pmatrix}$$

$$\beta = \begin{pmatrix} \mu + \alpha_k \\ \alpha_1 - \alpha_k \\ \alpha_2 - \alpha_k \\ \dots \\ \alpha_{k-1} - \alpha_k \end{pmatrix}$$

Obviously, the new design matrix $\mathbf{X}$ has a full rank k . The first component of the parameter vector β is the expectation of the last sample. The further components of the parameter vector β denote differential effects; they measure the effect of the j th sample minus the effect of the last sample.

EXAMPLE 8 OF TOTAL PROTEIN IN SERUM

The new design matrix $\mathbf{X}$ and the new parameter vector β for the one-way model are:

$$\mathbf{X} = \begin{pmatrix} \mathbf{1}_{12} & \mathbf{1}_{12} & \mathbf{0}_{12} \\ \mathbf{1}_{12} & \mathbf{0}_{12} & \mathbf{1}_{12} \\ \mathbf{1}_{12} & \mathbf{0}_{12} & \mathbf{0}_{12} \end{pmatrix} \quad \beta = \begin{pmatrix} \mu + \alpha_3 \\ \alpha_1 - \alpha_3 \\ \alpha_2 - \alpha_3 \end{pmatrix}$$

This matrix $\mathbf{X}$ has full rank, so the matrix $\mathbf{X}^T\mathbf{X}$ is regular. The following computations can be performed by hand or by means of a computer algebra system like Mathematica®:

$$\mathbf{X}^T\mathbf{X} = \begin{pmatrix} 36 & 12 & 12 \\ 12 & 12 & 0 \\ 12 & 0 & 12 \end{pmatrix}$$

$$(\mathbf{X}^T\mathbf{X})^{-1} = \begin{pmatrix} \frac{1}{12} & \frac{1}{12} & \frac{-1}{12} \\ \frac{-1}{12} & \frac{1}{6} & \frac{1}{12} \\ \frac{-1}{12} & \frac{1}{12} & \frac{1}{6} \end{pmatrix}$$

The normal equations are solved uniquely by the estimation vector:

$$\mathbf{b} = \begin{pmatrix} 6.6500 \\ -1.18333 \\ -0.883333 \end{pmatrix}$$

Comparing these results with the SAS output of the procedure GLM, it is obvious that the only meaningful difference is the missing part of the 4th component. The estimates computed by SAS by means of a generalized inverse are unbiased estimators for the new set of parameters: The number 6.6500 estimates the expectation $\mu + \alpha_3$ of the TPRO value in the species Dog. For the species Mouse, the expectation of the TPRO value is $\mu + \alpha_1 = (\mu + \alpha_3) + (\alpha_1 - \alpha_3)$. It can be estimated by $6.6500 + (-1.18333) = 5.4667$. For the species Rat, the expectation of the TPRO value is $\mu + \alpha_2 = (\mu + \alpha_3) + (\alpha_2 - \alpha_3)$. It can be estimated by $6.6500 + (-0.883333) = 5.7667$.

Obviously, these estimators are identical with the averages $\bar{y}_1$, $\bar{y}_2$, and $\bar{y}_3$ of the three samples corresponding to the single species which were computed by the SAS procedure MEANS, and the question arises if this linear model is worth the effort. Moreover, it has to be admitted that for a one-way ANOVA, it would be possible to avoid a less-than-full-rank design matrix $\mathbf{X}$ in choosing a no-intercept model where the design matrix $\mathbf{X}$ arises from the original design matrix by canceling the first column. For the no-intercept linear model, the design matrix and the parameter vector are given by:

$$\mathbf{X} = \begin{pmatrix} \mathbf{1}_{12} & \mathbf{0}_{12} & \mathbf{0}_{12} \\ \mathbf{0}_{12} & \mathbf{1}_{12} & \mathbf{0}_{12} \\ \mathbf{0}_{12} & \mathbf{0}_{12} & \mathbf{1}_{12} \end{pmatrix} \quad \beta = \begin{pmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \end{pmatrix}$$

The justification for leaving out the possibility of a no-intercept model is the fact that this method does not work in the case of a two-way ANOVA, as the sum of the last p columns again gives a column where all elements have a value of 1. So we have to go on with the method of recoding the $1 + r + p$ parameters. For the sake of simplicity, we demonstrate the following method for our example.

EXAMPLE 9 OF TOTAL PROTEIN IN SERUM

We make use of the fact that for every i , the following equations are true:

$$x_{i0} = 1, \quad x_{i1} + x_{i2} + x_{i3} = 1, \quad x_{i4} + x_{i5} = 1$$

So the model can be rewritten in the following form:

$$\begin{aligned} Y_i &= \mu x_{i0} + \alpha_1 x_{i1} + \alpha_2 x_{i2} + \alpha_3 x_{i3} + \beta_1 x_{i4} + \beta_2 x_{i5} + E_i \\ &= \mu x_{i0} + \alpha_1 x_{i1} + \alpha_2 x_{i2} + \alpha_3 x_{i3} + \beta_1 x_{i4} + \beta_2 x_{i5} + E_i \\ &\quad + (\alpha_3 + \beta_2) x_{i0} - \alpha_3 (x_{i1} + x_{i2} + x_{i3}) - \beta_2 (x_{i4} + x_{i5}) \\ &= (\mu + \alpha_3 + \beta_2) x_{i0} + (\alpha_1 - \alpha_3) x_{i1} + (\alpha_2 - \alpha_3) x_{i2} \\ &\quad + (\beta_1 - \beta_2) x_{i4} + E_i \end{aligned}$$

The design matrix $\mathbf{X}$ of this linear model has four columns instead of six and the parameter vector $\boldsymbol{\beta}$ has four components instead of six:

$$\mathbf{X} = \begin{pmatrix} \mathbf{1}_6 & \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{1}_6 \\ \mathbf{1}_6 & \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{0}_6 \\ \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{1}_6 & \mathbf{1}_6 \\ \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{1}_6 & \mathbf{0}_6 \\ \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{0}_6 & \mathbf{1}_6 \\ \mathbf{1}_6 & \mathbf{0}_6 & \mathbf{0}_6 & \mathbf{0}_6 \end{pmatrix} \quad \boldsymbol{\beta} = \begin{pmatrix} \mu + \alpha_3 + \beta_2 \\ \alpha_1 - \alpha_3 \\ \alpha_2 - \alpha_3 \\ \beta_1 - \beta_2 \end{pmatrix}$$

Obviously, the new design matrix $\mathbf{X}$ has a full rank of 4. The first component of the parameter vector $\boldsymbol{\beta}$ is the expectation of the last sample (i.e., of male rats). The next two components of the parameter vector $\boldsymbol{\beta}$ again denote differential effects; they measure the effect of the species Dog minus the effect of the species Rat and the effect of the species Mouse minus the effect of the species Rat. The last component of $\boldsymbol{\beta}$ measures the differential effect of Sex: female minus male. Submitting the SAS commands:

```
proc glm data=TPRO;
class Species Sex;
model value=Species Sex/solution;
run;
```

yields the estimation:

$$\mathbf{b} = \begin{pmatrix} 6.70277778 \\ -1.18333333 \\ -0.90833333 \\ -0.10555556 \end{pmatrix}$$

with the note that the estimates are biased and not unique. Indeed, the output does not allow to compute unbiased estimators for the original parameters μ , α_1 , α_2 , α_3 , β_1 , and β_2 . But with the correct interpretation of the output, the expectation of the random variable TPRO for each of the six samples defined by Species and Sex can be estimated unbiasedly:

Dog, female	$6.70277778 - 1.18333333 - 0.10555556 \approx 5.41389$
Dog, male	$6.70277778 - 1.18333333 \approx 5.51944$
Mouse, female	$6.70277778 - 0.90833333 - 0.10555556 \approx 5.68889$
Mouse, male	$6.70277778 - 0.90833333 \approx 5.79444$
Rat, female	$6.70277778 - 0.10555556 \approx 6.59722$
Rat, male	$6.70277778 \approx 6.70278$

At the end of this contribution, we make some remarks concerning additional possibilities of the linear model. The

further discussion of these possibilities is beyond the scope of this article.

REMARK 1

Neither the method of generalized inverses nor the described method of recoding the parameters allows to compute unbiased estimators for the parameters μ , α_1 , α_2 , ..., α_k or μ , α_1 , ..., α_r , β_1 , ..., β_p of the original linear model of the one-way or the two-way ANOVA, respectively. But there are linear functions of these parameters for which unbiased estimates do exist. In the one-way case, all sums $\mu + \alpha_i$, $1 \leq i \leq k$ for instance can be estimated. In the two-way case, all sums $\mu + \alpha_i + \beta_j$, $1 \leq i \leq r$, $1 \leq j \leq p$ can be estimated.

REMARK 2

It was emphasized that for the task of estimating the parameters of a full-rank linear model, special distribution assumptions are not necessary. So up to now, in our example, the fact that the TPRO value can be assumed to be normally distributed was not taken advantage of. But with this normal distribution in mind, one can test the hypotheses on the parameters. SAS, for instance, automatically tests the hypothesis that this component has a value of 0 using a Student-distributed test variable for each component of the parameter vector. The output shows: The estimators for the intercept and for the differential effects “Dog minus Rat” and “Mouse minus Rat” differ significantly from 0, whereas the last component estimating the differential effect “Female minus Male” does not.

Within the frame of the linear model $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{E}$ of ANOVA, it is possible to test more general hypotheses of the form $\mathbf{C}\boldsymbol{\beta} = \mathbf{0}$. Here $\mathbf{C}$ is a matrix with an appropriate number of rows and columns. In the two-way model for the TPRO value for instance, the matrix $\mathbf{C}$ could have one single row: With $\mathbf{C} = (0 \ 1 \ 0 \ 0)$, the hypothesis $\mathbf{C}\boldsymbol{\beta} = \mathbf{0}$ means that $\alpha_1 - \alpha_3 = 0$ (i.e., there is no difference between the species Dog and the species Rat). With $\mathbf{C} = (0 \ 1 \ 0 \ -10)$, the hypothesis $\mathbf{C}\boldsymbol{\beta} = \mathbf{0}$ means that $\alpha_1 - \alpha_3 = 10(\beta_1 - \beta_2)$ (i.e., the difference between the effects of the species Dog and species Rat is 10 times as great as the difference between the effects Female and Male).

REMARK 3

In the linear model of a two-way or higher-way ANOVA, it is possible to include interactions. In the example of TPRO, there are six interaction parameters. Including them in the model increases the number of columns of the design matrix by six, but the rank is only increased by two. So one has to reduce the number of interaction terms from six to two, and it is rather difficult to explain the meaning of the recoded parameters.

REMARK 4

It should be mentioned that there is another recoding method for solving the problem of a less-than-full-rank design matrix in the linear model of ANOVA. Making use of the reparameterization conditions, the number of parameters for each factor variable can be reduced by 1. The resulting design matrix $\mathbf{X}$ has elements with values 0, +1, or -1. In the example of TPRO for instance, we have the two conditions $\alpha_1 + \alpha_2 + \alpha_3 = 0$ and $\beta_1 + \beta_2 = 0$. These two equations yield:

$$\alpha_3 = -\alpha_1 - \alpha_2 \quad \text{and} \quad \beta_2 = -\beta_1$$

So the original model equations can be rewritten in the following form:

$$\begin{aligned} Y_i &= \mu x_{i0} + \alpha_1 x_{i1} + \alpha_2 x_{i2} + \alpha_3 x_{i3} + \beta_1 x_{i4} + \beta_2 x_{i5} + E_i \\ &= \mu x_{i0} + \alpha_1 x_{i1} + \alpha_2 x_{i2} + (-\alpha_1 - \alpha_2) x_{i3} + \beta_1 x_{i4} \\ &\quad + (-\beta_1) x_{i5} + E_i \\ &= \mu x_{i0} + \alpha_1 (x_{i1} - x_{i3}) + \alpha_2 (x_{i2} - x_{i3}) \\ &\quad + \beta_1 (x_{i4} - x_{i5}) + E_i \end{aligned}$$

Again the design matrix $\mathbf{X}$ of this new linear model with only four columns instead of six has a full rank and the parameter vector β has four components instead of six:

$$\mathbf{X} = \begin{pmatrix} 1_6 & 1_6 & 0_6 & 1_6 \\ 1_6 & 1_6 & 0_6 & -1_6 \\ 1_6 & 0_6 & 1_6 & 1_6 \\ 1_6 & 0_6 & 1_6 & -1_6 \\ 1_6 & -1_6 & -1_6 & 1_6 \\ 1_6 & -1_6 & -1_6 & -1_6 \end{pmatrix} \quad \beta = \begin{pmatrix} \mu \\ \alpha_1 \\ \alpha_2 \\ \beta_1 \end{pmatrix}$$

The advantage of this reparameterization method is that the meaning of the parameters is left unchanged. This method is not supported by the SAS procedure GLM, but it is used in the procedure CATMOD for the linear model in categorical data analysis, where the response variable is categorical as well.^[3,6]

REMARK 5

In many animal studies, each animal is measured repeatedly through time. In the ideal case, the number of time

points is identical for each animal. Performing a one-way or a higher-way ANOVA in treating “time point” as a factor variable violates the primary assumption of independence.

There exist different methods for solving this problem. If the influence of time is negligible, the simplest method is to choose one value per animal. For example, one can choose the first observation, or one can choose one observed value at random. If (and only if) the set of time points is identical for each animal, a time-by-time ANOVA can be performed. It consists of a number of separate analyses, one for each time of observation.

The repeated-measures ANOVA, however, includes the influence of time. It requires a modification of the underlying linear model, adding further parameters for the interactions between treatments and time points. By the repeated statement, the SAS procedures ANOVA and GLM offer the opportunity of performing a repeated-measures ANOVA.

The repeated-measures ANOVA and further GLMs for the analysis of longitudinal data like marginal models, random effects models, and transition models are discussed in Ref. [1].

Abstract

For assessment of biosimilarity for biosimilar products, the United States (US) Food and Drug Administration (FDA) proposed a stepwise approach for providing the totality of the evidence of similarity between a proposed biosimilar product and a US-licensed (reference) product. The stepwise approach starts with assessment of critical quality attributes (CQAs) that are relevant to clinical outcomes in structural and functional characterization in the manufacturing process of the proposed biosimilar product. The FDA suggests that these CQAs be identified and classified into three tiers depending on their criticality or risk ranking. To assist the sponsors, the FDA also suggests some statistical approaches for the assessment of analytical similarity for CQAs from different tiers, namely equivalence test for Tier 1, quality range approach for Tier 2, and descriptive raw data and graphical comparison for Tier 3. In this article, challenging issues to the FDA's recommended approaches are discussed followed by alternative methods for the assessment of analytical similarity (mainly for CQAs from Tier 1).

Keywords: Equivalence test; Fixed SD approach; Quality range approach; Stepwise approach; Tiered approach; Totality of the evidence.

INTRODUCTION

In recent years, the assessment of biosimilarity for biosimilar products has received much attention by scientists, researchers, and reviewers from the pharmaceutical industry (biosimilar sponsors), academia, and regulatory agencies such as the United States Food and Drug Administration (FDA) and the China Food and Drug Administration (CFDA).^[6] As indicated in its recent guidance, the FDA recommends a stepwise approach for obtaining the totality of the evidence for demonstrating biosimilarity between a proposed biosimilar product and an innovative (reference) biological product.^[1,9] The stepwise approach starts with analytical studies for functional and structural characterization of critical quality attributes (CQAs) that are relevant to clinical outcomes at various stages of the manufacturing process followed by animal studies for assessment of toxicity, clinical pharmacology pharmacokinetic (PK) or pharmacodynamic (PD) studies, and clinical studies for assessment of immunogenicity, safety/tolerability, and efficacy.^[2,3,5] For the analytical studies, the FDA suggests that CQAs be identified and classified into three tiers according to their criticality or risk ranking based on the mechanism of action (MOA) or PK using appropriate

statistical models or methods. CQAs that are most relevant to clinical outcomes are classified as Tier 1, whereas CQAs that are less (mild-to-moderate) or least relevant to clinical outcomes are classified as Tier 2 and Tier 3, respectively.

The FDA proposes equivalence tests for CQAs in Tier 1, quality range approach for CQAs in Tier 2, and raw data or graphical presentation for CQAs in Tier 3 to assist sponsors in analytical similarity assessment for obtaining the totality of the evidence for demonstrating similarity between the proposed biosimilar product and the reference product.^[7,12] As indicated by the FDA, the equivalence test for Tier 1 CQAs is more statistically rigorous than that of the quality range approach for Tier 2 CQAs, which is in turn more rigorous than that of raw data or graphical presentation for Tier 3 CQAs.^[12] In practice, however, for a given CQA, there is no guarantee that passing a Tier 1 test will pass a Tier 2 test and vice versa. This has raised a number of debatable (controversial) issues in analytical similarity assessment.^[2,3,5] These issues include, but are not limited to, (1) fundamental similarity assumption, (2) primary assumptions for the tiered approach, (3) statistical properties of the FDA's recommended Tier 1 equivalence test, (4) criticism of the fixed approach for margin/range selection, (5) inconsistencies between tiered approaches,

(6) sample size requirement, (7) heterogeneity within lots and across lots within and between test product and reference product, (8) interpretation of the FDA's current thinking on scientific input, (9) relationship between similarity limit and variability, and (10) a proposed unified tiered approach.

Analytical similarity assessment is a complicated problem that involves characterization of bioactivity and protein content whose relationship with clinical outcomes may not be fully explored and understood. This uncertainty has made analytical similarity assessment even more complicated. The purpose of this article is to give a brief summary of these controversial issues in analytical similarity assessment rather than provide solutions.

FUNDAMENTAL SIMILARITY ASSUMPTION

For small-molecule drug products, bioequivalence studies are necessarily conducted for regulatory review and approval of small-molecule generic drug products.^[8] This is because it constitutes legal basis (from the *Hatch-Waxman* Act) under the *Fundamental Bioequivalence Assumption*, which states that

If two drug products are shown to be bioequivalent, it is assumed that they will reach the same therapeutic effect or they are therapeutically equivalent.

Under the Fundamental Bioequivalence Assumption, bioavailability (defined as the rate and extent of drug absorbed into the bloodstream and become available) serves as a surrogate endpoint for clinical outcomes (safety and efficacy). Thus, under the Fundamental Bioequivalence Assumption, an *approved* generic drug product can serve as a substitute for the innovative (brand-name) drug product. Although this Fundamental Bioequivalence Assumption constitutes legal basis, it has been challenged by many researchers. In practice, there are following four possible scenarios:

1. Drug absorption profiles are similar, and they are therapeutic equivalent.
2. Drug absorption profiles are not similar, but they are therapeutic equivalent.
3. Drug absorption profiles are similar, but they are not therapeutic equivalent.
4. Drug absorption profiles are not similar, and they are not therapeutic equivalent.

The Fundamental Bioequivalence Assumption is considered scenario 1. Scenario 1 works if the drug absorption (in terms of the rate and extent of absorption) is predictive of clinical outcome. In this case, PK responses such as AUC (area under the blood or plasma concentration–time curve for measurement of the extent of drug absorption) and C_{max} (maximum concentration for measurement of the rate of

drug absorption) serve as surrogate endpoints for clinical endpoints for the assessment of efficacy and safety of the test product under investigation. Scenario 2 is the case in which generic companies argue for generic approval of their drug products especially when their products fail to meet regulatory requirement for bioequivalence. In this case, it is doubtful that there is a relationship between PK responses and clinical endpoints. The innovator companies usually argue with the regulatory agency for generic approval with scenario 3. However, more studies are necessarily conducted in order to verify scenario 3. There are no arguments with respect to scenario 4.

It should be noted that a generic drug contains *identical* active ingredient(s) as the brand-name drug. Thus, it is reasonable to assume that the generic (test) drug products and the brand-name (reference) drug products have identical means, i.e., $\mu_T = \mu_R$. In addition, bioequivalence testing focuses on the mean difference (i.e., $\mu_T - \mu_R$) or the ratio of means (i.e., μ_T / μ_R) and ignores heterogeneity in variability of the test and reference products (i.e., $\sigma_T \neq \sigma_R$). As a result, a generic drug product may fail the bioequivalence testing when σ_R is relatively large (say > 30%) even when $\mu_T = \mu_R$. Unlike small-molecule drug products, biosimilar products are large-molecule drug products which are made of living cells or living organisms. Chow et al.^[4] indicated that there are fundamental differences between small-molecule drug products and biosimilar products. For example, biosimilar products are often very sensitive to environmental factors during the manufacturing process. A small change and variation may translate to a huge change in clinical outcomes. Consequently, biosimilar products are expected to have much larger variability compared to that of generic drug products. In this case, statistical methods for similarity assessment following the concept of bioequivalence testing (i.e., focusing on the mean difference or the ratio of means but ignoring variability) for assessing the biosimilarity of biosimilar products may not be appropriate. [Table 1](#) provides a comparison between bioequivalence test for generic drug products and biosimilarity test for biosimilar products.

Following a similar idea to bioequivalence assessment for small-molecule drug products, Scientific Statistical Advisory Board on Biosimilars^[11] proposed the following Fundamental Similarity Assumption:

When a follow-on biologic product is claimed to be biosimilar to an innovator product in some well-defined study endpoints, it is assumed that they will reach similar therapeutic effect or they are therapeutically equivalent.

Although the aforementioned proposed Fundamental Similarity Assumption does not constitute legal basis, the FDA seems to adopt the assumption for analytical similarity assumption without verifying the validity of the assumption. In other words, the FDA assumes that analytical similarity in terms of CQAs identified at various stages

Table 1 Comparison of Bioequivalence and Biosimilarity Testing

Characteristics	Bioequivalence		Biosimilarity	
	In vitro BE testing	In vivo BE testing	Analytical	PK/clinical
Fundamental assumption	√	√	×	×
Log data	×	√	×	×

Criterion	(90%, 111%)	(80%, 125%)	$EAC = \pm 1.5\sigma_R$	SABE?
Analysis	Profile/non-profile	Hypothesis/CI	Hypothesis/CI	Hypothesis/CI Biosimilarity index

such as functional and structural characterization of the manufacturing process is predictive of clinical outcomes.

For biosimilars, it can be expected that $\mu_T \neq \mu_R$ and $\sigma_T \neq \sigma_R$, i.e., $\mu_T = \mu_R + \Delta$ and $\sigma_T = C\sigma_R$, where Δ is the true mean difference and C is an inflation factor for the variability.

PRIMARY ASSUMPTIONS FOR THE TIERED APPROACH

Tier 1 Equivalence Test

For CQAs in Tier 1, the FDA recommends that an equivalence test be performed for assessing analytical similarity. As indicated by the FDA, for a given CQA, we may test for equivalence by the following interval (null) hypothesis:

$$H_0: \mu_T - \mu_R \leq -\delta \text{ or } \mu_T - \mu_R \geq \delta,$$

where $\delta > 0$ is the equivalence limit (or similarity margin), and μ_T and μ_R are the mean responses of the test (the proposed biosimilar) product and reference product lots, respectively. Analytical equivalence (similarity) is concluded if the null hypothesis of nonequivalence (*dis-similarity*) is rejected. Note that inequivalence can be defined as when the confidence interval falls entirely outside the equivalence limits. Similarly to the confidence interval approach for bioequivalence testing under the raw data model, analytical similarity would be accepted for a quality attribute if the $(1 - 2\alpha)100\%$ two-sided confidence interval of the mean difference is within $(-\delta, \delta)$. The FDA further recommended that the equivalence acceptance criterion (EAC), $\delta = EAC = 1.5\sigma_R$, where σ_R is the variability of the reference product being used based on extensive simulation studies and internal scientific input. Chow^[3] provided statistical justification for the selection of $c = 1.5$ in EAC following the idea of scaled average bioequivalence (SABE) criterion for highly variable drug products proposed by the FDA.^[10]

For the establishment of EAC, the FDA made the following assumptions: First, the FDA assumes that the true

difference in means is proportional to σ_R , i.e., $\mu_T - \mu_R$ is proportional to σ_R . Second, the FDA adopts the similarity limit as $EAC = 1.5\sigma_R$ and recommends that σ_R be estimated by the sample standard deviation (SD) of test values from reference lots (one test value from each lot). Third, in the interest of achieving a desired power of the similarity test, the FDA further recommends that an appropriate sample size be selected by evaluating the power under the alternative hypothesis at $\mu_T - \mu_R = \frac{1}{8}\sigma_R$. The assumption that $\mu_T - \mu_R$ is proportional to σ_R , the selection of $c = 1.5$, and the allowed mean shift of $\mu_T - \mu_R = \frac{1}{8}\sigma_R$ have generated tremendous discussion among the FDA, biosimilar sponsors, and academia, and they are debatable.

To provide a better understanding of the debatable issue and the FDA's proposal, we would like to point out the following, which may be helpful to resolve the debatable issues: (1) unlike the traditional bioequivalence test, the FDA's intention is to take variability into account by considering the effect size adjusted for variability, i.e.,

$$\text{Effect size} = \text{eff} = \frac{\mu_T - \mu_R}{\sigma_R} = \frac{\frac{1}{8}\sigma_R}{\sigma_R} = \frac{1}{8} = 0.125,$$

which is halfway between 1 and 1.25 (unity to the upper equivalence limit of 125%); (2) the EAC for effect size adjusted for variability becomes fixed, i.e., $EAC = c = 1.5$; and (3) if the true difference falls on the halfway between 1 and 1.25, the worst possible observed difference could fall on 1.25 (this may happen if the worst possible reference lot is selected for comparison). In this case, the original EAC (bioequivalence testing for generic drug products with $\mu_T = \mu_R$) is necessarily shifted by 0.25. Thus, the upper limit is shifted from 1.25 to $c = 1.25 + 0.25 = 1.5$.

Tier 2 Quality Range Approach

For CQAs in Tier 2, the FDA suggests that analytical similarity be performed based on the concept of quality ranges, i.e., $\pm x\sigma_R$, where σ_R is the SD of the reference product and x is a constant which should be

appropriately justified. Thus, the quality range of the reference product for a specific quality attribute is defined as $(\hat{\mu}_R - x\hat{\sigma}_R, \hat{\mu}_R + x\hat{\sigma}_R)$. Analytical similarity would be accepted for the quality attribute if a sufficiently large percentage of test lot values falls within the quality range. Under normality assumption, if $x = 1.645$, we would expect 90% of the test results from reference lots to lie within the quality range. If x is chosen to be 1.96, we would expect that about 95% test results of reference lots will fall within the quality range. Thus, the selection of x could have an impact on the width of the quality range and consequently the percentage of test lot values that will fall within the quality range.

At the 2015 Duke Industry Statistics Symposium held in Duke Campus on October 22–23, one of the FDA speakers indicated that x should be selected between 2 and 3 to guarantee that the majority of test values of the test lots will fall within the quality range established based on the test values of the reference lots. Under the normality assumption, in practice, we would expect that there are about 95% of data would fall within $\pm 2SD$ (i.e., $x = 2$) of the mean, and about 99.7% of data would fall within $\pm 3SD$ (i.e., $x = 3$) of the mean. Under the normality assumption, the FDA recommended the quality range approach; it is considered a reasonable approach only under the assumption that $\mu_T \approx \mu_R$ and $\sigma_T \approx \sigma_R$. In this case, it can be expected that the majority of test values obtained from the test lots will fall within $\pm xSD$ of the range established based on the test values of the reference lots.

In practice, however, the assumption that $\mu_T \approx \mu_R$ and $\sigma_T \approx \sigma_R$ are usually not true due to the nature of biosimilar products. Thus, one of the major criticisms of the quality range approach is that it ignores the fact that there are differences in population mean and population SD between the proposed biosimilar product and the reference product, i.e., $\mu_T \neq \mu_R$ and $\sigma_T \neq \sigma_R$. In practice, it is recognized that biosimilarity between a proposed biosimilar product and a reference product could be established even under the assumption that $\mu_T \neq \mu_R$ and $\sigma_T \neq \sigma_R$. Thus, under the assumption that $\mu_T \approx \mu_R$ and $\sigma_T \approx \sigma_R$, the quality range approach for analytical similarity assessment for CQAs from Tier 2 is considered more stringent compared to equivalence testing for CQAs from Tier 1 (most relevant to clinical outcomes), regardless of the fact that they are mild-to-moderate relevant to clinical outcomes. This is because that equivalence testing allows a possible mean shift of $\sigma_R/8$, whereas the quality range approach does not. In practice, there are several possible scenarios that include the cases where (1) $\mu_T \approx \mu_R$ or there is a significant mean shift (either a shift to the right or a shift to the left), and (2) $\sigma_T \approx \sigma_R$, $\sigma_T > \sigma_R$, or $\sigma_T < \sigma_R$.

Thus, one of the most controversial issues for the quality range approach for CQAs in Tier 2 is that the approach does not reflect the real practice that $\mu_T \neq \mu_R$ and $\sigma_T \neq \sigma_R$. As a result, the test results are somewhat misleading and not reliable.

Tier 3 Raw Data and Graphical Comparison

For CQAs in Tier 3 with the lowest risk ranking, the FDA recommends an approach that uses raw data/graphical comparisons. The examination of similarity for CQAs in Tier 3 by no means is less stringent, which is acceptable because they have least impact on clinical outcomes in the sense that a notable dis-similarity will not affect clinical outcomes.

Evaluation based on raw data and graphical presentation is not only somewhat subjective but also biased. Tier 1 equivalence tests and Tier 2 quality range similarity tests are supposed to be more rigorous than Tier 3 raw data and graphical comparison. That is, passing the Tier 1 equivalence test and Tier 2 quality range similarity test will pass the Tier 3 raw data and graphical comparison test. In practice, however, there is no guarantee that a given CQA that passes a Tier 1 equivalence test or Tier 2 quality range similarity test will pass a Tier 3 raw data and graphical comparison test and vice versa. Since CQAs in Tier 3 are considered least relevant to clinical outcomes, it is necessary that all Tier 3 CQAs pass the test. If not, it is of interest to know about what percentage of CQAs need to pass in order to pass a Tier 3 test.

STATISTICAL PROPERTIES OF THE FDA'S TIER 1 EQUIVALENCE TEST

For equivalence test for CQAs in Tier 1, the FDA recommends testing one sample from each reference lot for obtaining an estimate of σ_R . Wang and Chow^[13] evaluated statistical properties of the FDA's recommended method. Without loss of generality, suppose multiple test samples from each reference lot are available. Let x_{Rij} be the test value of the j th test sample from the i th reference lot, $i = 1, \dots, k, j = 1, \dots, n_i$, and it follows a normal distribution with mean μ_i and variance σ_i^2 , where μ_i and σ_i^2 are also random variables. The expectations of μ_i and σ_i^2 are μ and σ^2 , and the variances are σ_μ^2 and σ_σ^2 . Then, the variance of x_{Rij} is given by

$$\begin{aligned}\sigma_R^2 &= \text{Var}(x_{Rij}) \\ &= \text{Var}\left(E(x_{Rij} | \mu_i, \sigma_i^2)\right) + E\left(\text{Var}(x_{Rij} | \mu_i, \sigma_i^2)\right) \\ &= \text{Var}(\mu_i) + E(\sigma_i^2) = \sigma_\mu^2 + \sigma^2.\end{aligned}$$

Define $\bar{x}_{Ri} = \frac{1}{n_i} \sum_{j=1}^{n_i} x_{Rij}$, $\bar{x}_R = \frac{1}{k} \sum_{i=1}^k \bar{x}_{Ri}$. Then,

$$\begin{aligned}E(\bar{x}_{Ri}) &= \frac{1}{n_i} \sum_{j=1}^{n_i} E(x_{Rij} | \mu_i) = \frac{1}{n_i} \sum_{j=1}^{n_i} E(\mu_i) = \mu \\ \text{Var}(\bar{x}_{Ri}) &= \text{Var}\left(E(\bar{x}_{Ri} | \mu_i, \sigma_i^2)\right) + E\left(\text{Var}(\bar{x}_{Ri} | \mu_i, \sigma_i^2)\right) \\ &= \text{Var}(\mu_i) + \frac{1}{n_i} E(\sigma_i^2) = \sigma_\mu^2 + \frac{1}{n_i} \sigma^2,\end{aligned}$$

where

$$E(\bar{x}_{R..}) = \frac{1}{k} \sum_{i=1}^k E(\bar{x}_{Ri.}) = \mu$$

$$Var(\bar{x}_{R..}) = \frac{1}{k^2} \sum_{i=1}^k Var(\bar{x}_{Ri.}) = \frac{1}{k} \sigma_{\mu}^2 + \frac{\sigma^2}{k^2} \left(\sum_{i=1}^k n_i \right)$$

If we assume that $n_1 = \dots = n_k = n$, then we have

$$\hat{\sigma}_R^2 = \frac{1}{nk-1} \sum_{i=1}^k \sum_{j=1}^{n_i} (x_{Rij} - \bar{x}_{R..})^2$$

$$E(\hat{\sigma}_R^2) = \frac{1}{nk-1} \sum_{i=1}^k \sum_{j=1}^{n_i} E \left((x_{Rij} - \mu)^2 + (\bar{x}_{R..} - \mu)^2 - 2(x_{Rij} - \mu)(\bar{x}_{R..} - \mu) \right)$$

$$= \frac{1}{nk-1} \sum_{i=1}^k \sum_{j=1}^{n_i} (Var(x_{Rij}) - Var(\bar{x}_{R..}))$$

$$= \frac{1}{nk-1} (n(k-1)\sigma_{\mu}^2 + (nk-1)\sigma_{\mu}^2) = \sigma_{\mu}^2 + \sigma^2 - \frac{n-1}{nk-1} \sigma_{\mu}^2.$$

Thus, it can be seen that the FDA's approach is an unbiased estimate of σ_R . However, when $n > 1$, the FDA's recommended approach with multiple test samples per lot is a biased estimate of σ_R . In the interest of having an unbiased estimate with multiple test samples per lot, Wang and Chow^[13] proposed an alternative approach to correct the biasedness. As indicated by Wang and Chow,^[13] multiple test samples per lot provide valuable information regarding the heterogeneity across lots, which is useful especially when extreme lots (i.e., lots with extremely low or high variability) are selected for equivalence test.

ISSUES OF FIXED MARGIN/RANGE IN THE TIERED APPROACH

In the tiered approach, the FDA seems to prefer a *fixed margin approach* for EAC by treating $s = \hat{\sigma}_R$ as the true σ_R (i.e., $1.5\sigma_R$) for Tier 1 CQAs. The fixed margin approach is also referred to as a *fixed SD approach* for similarity quality range by treating the estimate of SD (which is obtained based on the test values of reference lots) as the true σ_R (i.e., xSD) for Tier 2 CQAs. The fixed margin or SD is in fact a statistic, which is a random variable rather than a fixed constant. In other words, it may vary depending upon the selected reference lots for tiered testing. The fixed SD approach is a conditional approach rather than an unconditional approach. In practice, if reference lots with *less* variability are selected for tiered testing, the proposed biosimilar product is most likely to fail the test. As

a result, the scientific validity of the fixed SD approach is questionable.

One of the major criticisms of the fixed approach for margin/range selection in tiered analysis is that the fixed approach does not take into consideration the variability of the estimate of the SD. Thus, it is considered *bad luck* to the biosimilar sponsors if reference lots with less variability are selected for a Tier 1 equivalence test. Another criticism is that the reference product cannot pass a Tier 1 equivalence test itself if we divide all of the reference lots into two groups: one group with less variability and the other group with large variability. In this case, the group with large variability may not pass a Tier 1 equivalence test with EAC established based on the test values from the reference lots with less variability. It would be a concern that the reference product cannot pass a Tier 1 equivalence test when comparing to itself.

INCONSISTENT RESULTS BETWEEN TIERED APPROACHES

As indicated in Tsong,^[12] a Tier 1 equivalence test is considered more rigorous than a Tier 2 quality range approach, which is in turn more rigorous than a Tier 3 raw data and graphical comparison. The primary assumptions for these tiered approaches, however, are different. Thus, under different assumptions, there is no guarantee that passing a Tier 1 equivalence test will pass a Tier 2 quality range approach and vice versa although these tests are conducted based on the same data set collected from the test and reference lots under study. In practice, it is of interest to evaluate inconsistencies regarding the passages between a Tier 1 equivalence test and Tier 2 quality range approach.

For a given CQA, the inconsistencies between a Tier 1 equivalence test and a Tier 2 quality range approach can be assessed by means of clinical trial simulation as follows: Let p_{ij} be the probability of passing the i th tier test given that the CQA has passed the j th tier test. Thus, we have the following 2×2 contingency table for comparison between a Tier 1 equivalence test and Tier 2 quality range approach (Table 2).

Let $\mu_T = \mu_R + \Delta$ and $\sigma_T = C\sigma_R$. It is then suggested that the inconsistencies between a Tier 1 equivalence test and Tier 2 quality range approach be evaluated at various combinations of (1) $\Delta = 0$ (no mean shift), $\frac{1}{8}\sigma_R$ (FDA recommended mean shift allowed), and $\frac{1}{4}\sigma_R$ (the worst possible

Table 2 Probabilities of Inconsistencies

Tier 1 equivalence test	Tier 2 quality range approach	
	Pass	Fail
Pass	p_{11}	p_{12}
Fail	p_{21}	p_{22}

scenario); and (2) $C = 0.8$ (deflation), 1.0, and 1.2 (inflation) to provide a complete picture of the relative performance of a Tier 1 equivalence test and Tier 2 quality range approach.

SAMPLE SIZE REQUIREMENT

One of the most commonly asked questions for analytical similarity assessment is probably that of how many reference lots are required for establishing an acceptable EAC to achieve a desired power. For a given EAC, formulas for sample size calculation under different study designs are available in the work of Chow, Shao, and Wang (2008). In general, sample size (the number of reference lots, k) required is a function of (1) overall type I error rate (α), (2) type II error rate (β) or power ($1 - \beta$), (3) clinically or scientifically meaningful difference (i.e., $\mu_T - \mu_R$), and (4) the variability associated with the reference product (i.e., σ_R) assuming that $\sigma_T = \sigma_R$. Thus, we have

$$k = f(\alpha, \beta, \mu_T - \mu_R, \sigma).$$

In practice, we select an appropriate k for achieving a desired power of $1 - \beta$ for detecting a clinically meaningful difference of $\mu_T - \mu_R$ at a prespecified level of significance α , assuming that the true variability is σ . If α , $\mu_T - \mu_R$, and σ are fixed, the above equation becomes $k = f(\beta)$. We can then select an appropriate k for achieving the desired power. The FDA's recommendation attempts to control all parameters at the desired levels (e.g., $\alpha = 0.05$ and $1 - \beta = 0.8$) by *knowing* that $\mu_T - \mu_R$ and σ are varying. In practice, it is often difficult, if not impossible, to control (or find a balance point among) α (type I error rate), $1 - \beta$ (power), $\mu_T - \mu_R = \Delta$ (clinically meaningful difference), and σ (variability in observing the response) *at the same time*. For example, controlling α at a prespecified level of significance may be at the risk of decreasing power with a selected sample size.

HETEROGENEITY WITHIN/BETWEEN LOTS WITHIN/BETWEEN TEST AND REFERENCE PRODUCTS

Suppose there are n_R and n_T lots for analytical similarity assessment. For a given reference (test) lot, assume that the test value follows a distribution with mean μ_{Ri} (μ_{Ti}) and variance σ_{Ri}^2 (σ_{Ti}^2). FDA's recommended approach assumes that $\mu_{Ri} = \mu_{Rj}$ and $\sigma_{Ri}^2 = \sigma_{Rj}^2$ for $i \neq j, i, j = 1, \dots, n_R$ and $\mu_{Ti} = \mu_{Tj}$ and $\sigma_{Ti}^2 = \sigma_{Tj}^2$ for $i \neq j, i, j = 1, \dots, n_T$ for equivalence test in Tier 1 and quality range approach in Tier 2. Now let σ_R^2 and σ_T^2 be the variabilities associated with the reference product and the test product, respectively. Thus, we have

$$\sigma_R^2 = \sigma_{WR}^2 + \sigma_{BR}^2 \text{ and } \sigma_T^2 = \sigma_{WT}^2 + \sigma_{BT}^2,$$

where $\sigma_{WR}^2, \sigma_{BR}^2$ and $\sigma_{WT}^2, \sigma_{BT}^2$ are the within-lot variability and the between-lot (lot-to-lot) variability for the reference product and the test product, respectively. In practice, it is very likely that $\sigma_R^2 \neq \sigma_T^2$ and often $\sigma_{WR}^2 \neq \sigma_{WT}^2$ and $\sigma_{BR}^2 \neq \sigma_{BT}^2$ even when $\sigma_R^2 \approx \sigma_T^2$. This has posted a major challenge to the FDA's proposed approaches for the assessment of analytical similarity for CQAs from both Tier 1 and Tier 2, especially when there is only one test sample from each lot from the reference product and the test product. FDA's proposal ignores within-lot variability, i.e., when $\sigma_{WR}^2 = 0$ or $\sigma_R^2 = \sigma_{BR}^2$. In other words, sample variance based on $x_i, i = 1, \dots, n_R$ from the reference product may underestimate the true σ_R^2 and consequently may not provide a fair and reliable assessment of analytical similarity for a given quality attribute.

In practice, it is well recognized that $\mu_{Ri} \neq \mu_{Rj}$ and $\sigma_{Ri}^2 \neq \sigma_{Rj}^2$ for $i \neq j$, where μ_{Ri} and σ_{Ri}^2 are the mean and variance of the i th lot of the reference product. A similar argument is applied to the proposed biosimilar (test) product. As a result, the selection of reference lots for the estimation of σ_R is critical for the proposed approach. The selection of reference lots has an impact on the estimation of σ_R and consequently on the EAC. Assuming that $n_R > n_T$, the FDA suggested using the remaining $n_R - n_T$ lots to establish EAC to avoid selection bias. It sounds a reasonable approach if $n_R \gg n_T$. In practice, however, there might be a few lots available. Alternatively, it is suggested that all of the n_R lots be used to establish EAC.

The assumption that $\mu_{Ri} = \mu_{Rj}$ and $\sigma_{Ri}^2 = \sigma_{Rj}^2$ for $i \neq j; i, j = 1, \dots, n_R$ and $\mu_{Ti} = \mu_{Tj}$ and $\sigma_{Ti}^2 = \sigma_{Tj}^2$ for $i \neq j; i, j = 1, \dots, n_T$ is a strong assumption that does not reflect real practice. Since biosimilar products are made of living cells and/or living organisms, it is expected that

$$\mu_{Ri} \neq \mu_{Rj}, \sigma_{Ri}^2 \neq \sigma_{Rj}^2 \text{ for } i \neq j; i, j = 1, \dots, n_R$$

$$\mu_{Ti} \neq \mu_{Tj}, \sigma_{Ti}^2 \neq \sigma_{Tj}^2 \text{ for } i \neq j; i, j = 1, \dots, n_T.$$

Heterogeneity within lots and across lots between the test product and the reference product has posted the following controversial issues in analytical similarity assessment. First, suppose two extreme reference lots, one lot with the smallest within-lot variability and the other lot with the largest within-lot variability, are randomly selected for analytical similarity assessment. In this case, chances are that the reference product (the two selected extreme lots) may not even pass the equivalence test itself. Thus, analytical similarity between the test product and the reference product is not comprehensive. The other controversial issue is that if reference lots selected for establishment of EAC are extreme lots with the smallest variability, the established EAC could be too narrow to penalize good test products.

THE FDA'S CURRENT THINKING ON SCIENTIFIC INPUT

In his recent presentation, Tsong^[12] indicated that FDA's current thinking for establishment of EAC is to consider $1.5\sigma_R + \Delta$, where Δ is a regulatory allowance depending upon *scientific input*. From a statistical perspective, we may interpret the scientific input as scientific justification for accounting for the worst possible reference lot (i.e., a reference lot with extremely large variability) in establishment of EAC. Thus, $1.5\sigma_R + \Delta$, can be rewritten as $1.5\sigma'_R$, where $\sigma'_R = \sigma_R + \varepsilon$. Thus, we have

$$\text{EAC} = \pm 1.5(\sigma_R + \varepsilon).$$

The FDA's original proposal is to estimate σ'_R using sample SD (s) of the test values obtained from the reference lots, assuming that there is only one single test value per lot. Although Wang and Chow^[13] showed that s is an unbiased estimate of σ_R , it underestimates σ'_R because it does not take the variability associated with s into consideration. Thus, Chow^[3] suggested using the 95% upper confidence bound to estimate σ'_R , i.e.,

$$\hat{\sigma}'_R = \sqrt{\frac{n_R - 1}{\chi^2_{\alpha/2, n_R - 1}}} s.$$

This leads to

$$\varepsilon = \left(\sqrt{\frac{n_R - 1}{\chi^2_{\alpha/2, n_R - 1}}} - 1 \right) s.$$

One of the controversial issues for the establishment of EAC is whether the margin should be fixed. The FDA seems to recommend using the estimate of σ_R as the true σ_R without taking into consideration the variability associated with the observed sample variance. The variability associated with the observed sample variance depends upon the sample size (i.e., the number of reference lots) used for analytical similarity assessment. As a result, the result of an equivalence test may not be *reproducible*.

RELATIONSHIP BETWEEN SIMILARITY LIMIT AND VARIABILITY

As it can be seen from Table 1, similarity (equivalence) limit for assessment of similarity (equivalence) depends upon the variability associated with the drug product. For example, if the variability is less than 10%, (90%, 111%), similarity limit is recommended, while (80%, 125%) similarity limit is used for drug product with variability between 20% and 30%. For drug products with large variability (or highly variable drug products) such as biosimilar products, it is suggested that a scaled similarity limit

adjusted for variability be considered. As an alternative to the scaled similarity limit and in the interest of one-size-fits-all criterion, some researchers suggest (70%, 143%) to be considered. The selection of similarity limits based on the associated variability is somewhat arbitrary without scientific/statistical justification. In what follows, we attempt to describe the relationship between similarity limit and variability for achieving a desired probability of claiming similarity.

Let (δ_L, δ_U) be the similarity limits for the evaluation of similarity between a test product (T) and a reference product (R). Current regulation indicates that we can claim similarity if the 90% confidence interval of difference in mean (i.e., $\mu_T - \mu_R$) falls entirely within the lower and upper similarity limits. Let (L, U) be the 90% confidence interval for $\mu_T - \mu_R$. Define

$$p = P\{(L, U) \subset (\delta_L, \delta_U) | \sigma_R^2, \sigma_T^2\},$$

where σ_R^2 and σ_T^2 are the variabilities associated with the reference product and the test product, respectively, and p is a desired probability of claiming similarity. Thus, for a given set of p , σ_R^2 , and σ_T^2 , appropriate (δ_L, δ_U) can be determined.

A UNIFIED TIERED APPROACH

For biosimilar products, their population means and population variances are expected to be different. The relationship between a proposed biosimilar (test) product and an innovative (reference) product can be described as $\mu_T = \mu_R + \Delta$ and $\sigma_T = C\sigma_R$, where Δ is a measure of a possible shift in population mean and C is an inflation factor. There is a significant shift in mean (e.g., $\Delta \gg 0$) or notable heterogeneity between the proposed biosimilar product and the reference product (e.g., either $C \gg 1$ or $C \ll 1$). In this case, the validity of equivalence test for Tier 1 CQAs and the quality range approach for Tier 2 CQAs are questionable because the equivalence test and quality range approach are unable to handle a major shift in population mean and a significant change in population variance.

To overcome the problems of major mean shift and significant change in variability, alternatively, Chow et al.^[5] consider the equivalence test and quality range approach applied to standardized test values (or *effect size adjusted for SD*) rather than untransformed raw data. For simplicity and without loss of generality, consider the quality range approach for Tier 2 CQAs.

Define $eff_R = \mu_R / \sigma_R$ and $eff_T = \mu_T / \sigma_T$ and let $y_i, i = 1, \dots, n_R$ be the test values of the reference lots, where n_R is the number of reference lots considered for the test. Also, let $z_i, i = 1, \dots, n_T$ be the test values of the reference lots, where n_T is the number of test lots considered for the test. The FDA's quality range approach is applied

on $\{y_i, i = 1, \dots, n_R\}$ to establish the *quality range* with an appropriate selection of x . Instead, we suggested that the quality range approach be applied to $\{y_i / \hat{s}_R, i = 1, \dots, n_R\}$, where $\hat{s}_R$ is the sample SD of the test values of the reference lots. The quality range can then be established with the following adjustment on the selected x for achieving $eff_R \approx eff_T$. For simplicity and illustration purposes, consider that case that $\sigma_R \approx \sigma_T$ (i.e., $C \approx 1$). In this case, under the assumption that $eff_R \approx eff_T$, we have

$$\frac{\mu_R}{\sigma_R} \approx \frac{\mu_T}{\sigma_T} = \frac{\mu_R + \Delta}{\sigma_T}.$$

This leads to

$$\sigma_T = \sigma_R \left(1 + \frac{\Delta}{\mu_R} \right) \approx \sigma_R,$$

where $1 + \frac{\Delta}{\mu_R}$ is referred to as the adjustment factor for selection of x . Note that the left-hand side of the above equation is for test lots, and the right-hand side is referring to the reference lots. Various selection of x and adjusted x when there is a shift in mean are given in Table 3.

As it can be seen from the table, under the assumption that $eff_R \approx eff_T$, if there is a 20% shift in mean, i.e., $\frac{\Delta}{\mu_R} = 0.2$, the selection of $x = 2.5$ is equivalent to the selection of $x = 3$ without a shift in population mean.

A similar idea can be applied to the case in which there is a shift in scale parameter (i.e., $C \neq 1$). It should also be noted that the above proposal is similar to the justification (based on the percentage of coefficient of variation) as described in your questions. It should be noted that for biosimilar products, the assumption that $\mu_T \approx \mu_R$ and $\sigma_T \approx \sigma_R$ is usually not true. In practice, it is reasonable to assume that $eff_R \approx eff_T$. The above proposal accounts for possible shift in population mean and heterogeneity in variability.

Table 3 Adjustment on Selection of x When There Is a Shift in Mean

Δ/μ_R	x	$x(\text{adj})$
0.1	2	2.2
	2.5	2.75
	3	3.3
0.2	2	2.4
	2.5	3
	3	3.6

CONCLUDING REMARKS

The concept of stepwise approach recommended by the FDA is well taken. The purpose is to obtain the totality of the evidence in order for demonstration of biosimilarity between a proposed biosimilar product and an innovative biological product. The totality of the evidence consists of evidence from analytical studies for characterization of the molecule, animal studies for toxicity, PK and PD for pharmacological activities, and clinical studies for safety/tolerability, immunogenicity, and efficacy. The FDA, however, does not indicate whether these evidences should be obtained sequentially or simultaneously. It is a concern that a sequential approach may kill good products early purely by chance alone.

The stepwise approach starts with structural and functional characterization of CQAs that may be relevant to clinical outcomes. The FDA's recommended tiered approach is to serve the purpose. The recommended tiered approach depends upon the classification of identified CQAs based on their criticality (or risk ranking) relevant to clinical outcomes. The assessment of criticality, however, is somewhat subjective and often lack of scientific/statistical justification.

The FDA recommended that the tiered approach have raised a number of scientific and/or controversial issues. These controversial issues are related to difference in population means and heterogeneity within and across lots within and between the test product and the reference product. In practice, the primary assumption that $\mu_T \approx \mu_R$ and $\sigma_T \approx \sigma_R$ is usually not true. In this case, it is reasonable to assume that $eff_R = \frac{\mu_R}{\sigma_R} \approx \frac{\mu_T}{\sigma_T} = eff_T$ so that assessment of similarity between the proposed biosimilar product and the reference product is possible.

As indicated by Tsong,^[12] the Tier 1 equivalence test is supposed to be more rigorous than the Tier 2 quality range approach. Thus, we would expect that passing a Tier 1 test will pass a Tier 2 test. In practice, however, there is no guarantee that a given CQA that passes a Tier 1 test will pass a Tier 2 test and vice versa. This may be due to difference in primary assumptions made for Tier 1 equivalence test and Tier 2 quality range approach. Since there may be a large number of CQAs in both Tier 1 and Tier 2, "Does FDA require all CQAs at either Tier pass the corresponding test in order to claim the totality of the evidence?" is probably the most commonly asked question. If not, are there any rules to follow? These questions, however, remain unanswered.

Note that recently FDA circulated a draft guidance on analytical similarity assessment for public comments in September 2017. [14] In the draft guidance, most of the issues described in this chapter remained unsolved. Specific guidance on these issues are necessarily developed.

Abstract

The stability of a drug substance or drug product is its capacity to remain within the established acceptance criteria to ensure its identity, strength, quality, and purity for a specified period of time.

In this entry, the discussion focuses on the shelf life determination based on ANCOVA modeling.

INTRODUCTION

The stability of a drug substance or drug product is the capacity of the drug substance or drug product to remain within the established acceptance criteria to ensure its identity, strength, quality, and purity for a specified period of time. Regulatory agencies require that adequate testing be performed by an applicant to demonstrate the stability of the drug substance or product in support of a marketing registration application. The purpose of stability testing is to provide evidence on how the quality of a drug substance or drug product varies with time under the influence of a variety of environmental factors, such as temperature, humidity, and light. This assessment is used to establish the recommended storage condition and a shelf life for the drug product. Shelf life (also referred to as expiration dating period) is the period of time during which a drug product is expected to remain within the approved acceptance criteria, provided the drug product has been stored under the conditions defined on the container label.

For the sampling of stability data, a sufficient number of container units from each of at least three batches are put on long-term storage in a controlled environment (e.g., 25°C/60% RH), and samples are taken from the chamber at predetermined time points, namely at 0, 3, 6, 9, 12, 18, 24, 36, 48, etc. months, and tested for appropriate physical, chemical, biological, and microbiological attributes. The tested data of all time points collected before the drug is marketed will be used to support the marketing application of a drug product. A minimum of three batches is a compromise between cost and statistical requirements for estimating between-batch variability. Data analysis can determine

whether data from the batches could be combined, which usually lead to a longer shelf life estimate.

Many products are supplied in several strengths and different container closure systems, e.g., bottle, blister pack, and various container sizes and fills. In the United States, prior to 1990, the shelf life of a pharmaceutical product was determined separately for the individual manufacturing and marketing factors.^[1–3] It was realized that multifactorial designs in which the effects of batch, strength, container, etc. on the stability of the dosage form are investigated may be more efficient. If the assumption of equal error variances for various combinations of factors holds, there is a great potential advantage of the multifactorial over separate regression models. It lies in the improvement in the precision of the variance estimate by using all data. It lies also in the size of the estimation error through the potential pooling of data across design factors. In an effort to save cost and resources, several complicated multifactorial designs, most notably bracketing and matrixing designs, have been proposed in the early 1990s.^[4–8] However, their applicability to a given case needs to be cautiously evaluated.

The regulatory requirements of the submission of stability studies of pharmaceuticals at New Drug Application (NDA) or premarketing stage are described in the recently updated guidelines issued by the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use, or ICH. For example, *ICH Q1A(R) Stability Testing of New Drug Substances and Products*^[9] defines the core stability data requirements that are sufficient to support the registration of a new drug application in the tripartite regions of the European Union, Japan, and the United States. It recommends that at least three primary batches of the drug substance or product be tested for stability at prescribed storage conditions and time points. *ICH Q1D Bracketing*

This paper represents the authors' professional opinion but it does not represent an official position of the U.S. Food and Drug Administration.

and *Matrixing Designs for Stability Testing of New Drug Substances and Products*^[10] provides guidance on reduced designs for stability studies. It outlines the circumstances under which a bracketing or matrixing design can be used. *ICH Q1E Stability Data Evaluation*^[11] describes the principles of stability data evaluation and various approaches to statistical analysis of stability data when establishing a retest period for the drug substance or a shelf life for the drug product.

In this entry, the discussion focuses on the shelf life determination based on ANCOVA modeling.

ANCOVA MODELING AND POOLING TESTS

The linear change of the drug potency, or any other appropriate attribute, of an individual batch is often represented by

$$Y(t) = \alpha + \beta t + \varepsilon_i \quad (1)$$

where $Y(t)$ denotes the observed mean value of a batch at month t , α and β are the intercept and slope of the batch, respectively, ε_i is the model error term that follows a $N(0, \sigma^2)$ distribution. The true shelf life T of the batch is the date when the expected regression line intersects with either the lower acceptance criterion S_L or the upper acceptance criterion S_U . With the data collected, the shelf life is estimated by the earlier date (i.e., time point) between the two dates when either one of the two 95% confidence limits (upper and lower) of the expected regression line separately intersects the acceptance criteria, S_L and S_U .

Linear regressions of multiple batches of the same drug product can be represented by the ANCOVA model,

$$Y_i(t) = \alpha_0 + \alpha_i + (\beta_0 + \beta_i)t + \varepsilon_i t \quad (2)$$

where α_0 and β_0 are the common intercept and slope of all batches, respectively, α_i and β_i are the deviations of the individual intercept and slope of the i th batch from α_0 and β_0 , respectively.

Often the batches may share the same regression line or have the same changing rate (slope). In order to determine whether the batches share the same slope or intercept, pooling tests of slope and intercept are to be used. They are performed in a hierarchical order such that the poolability of the slope is tested before the intercept. To determine whether the batches share the same slope, one tests

$$H_{0\beta}: \beta_i = 0 \quad \text{vs.} \quad H_{a\beta}: \beta_i \neq 0 \quad (3)$$

If $H_{0\beta}$ is not rejected, one concludes that all batches share the same slope. In this case, one may proceed to test

$$H_{0\alpha}: \alpha_i = 0 \quad \text{vs.} \quad H_{a\alpha}: \alpha_i \neq 0 \quad (4)$$

Similarly, if $H_{0\alpha}$ is not rejected, one concludes that all batches share the same intercept as well.

Depending on the results of testing $H_{0\beta}$ and $H_{0\alpha}$, one can determine whether the batches should be pooled in estimating the shelf life using a common slope only or a common slope and intercept.

Conventionally, the modeling of simple stability studies with multiple batches is carried out with hierarchical pooling tests of slope and intercept^[1–3,13–16] based on the type I sums of squares when using the SAS PROC ANOVA or GLM.^[17] The two tests are performed in a single ANCOVA analysis of the model (2) using F -tests for hypotheses (3) and (4). With type I sums of squares, hypotheses (3) are tested using $R(\beta_i | \alpha_0, \beta_0, \alpha_i)$, i.e., the sum of squares of β_i adjusted for α_0 , β_0 , and α_i . Hypotheses (4) are tested with $R(\alpha_i | \alpha_0, \beta_0)$, i.e., the sum of squares of α_i adjusted for α_0 and β_0 . Once a model is determined, either testing or estimation of shelf life can be carried out using this final model.

The objective of the NDA stability study is to demonstrate that the sponsor can produce the same product consistently. This means that the same change over time occurs from batch to batch. It is expected that the sponsor can release batches within tightly controlled limits. The pooling tests are structured in a hierarchical order such that the slope test is carried out before the intercept test. The ANCOVA model (2) may be used to represent a common slope–common intercept (i.e., $\beta_i = 0$ and $\alpha_i = 0$) model, common slope–individual intercept (i.e., $\beta_i = 0$ and $\alpha_i \neq 0$) model, or an individual slope–individual intercept (i.e., $\beta_i \neq 0$ and $\alpha_i \neq 0$) model. In practice, the individual slope–common intercept model is not of interest and cannot be determined by hierarchical tests based on type I sums of squares in a single SAS PROC GLM run.

When evaluating the stability data in support of a single proposed shelf life T_0 for all batches of the drug product, the shortest estimated shelf life T^* of any batch in (2) will be compared with T_0 . T_0 is granted if $T^* > T_0$. T_0 may be extrapolated 6–12 months beyond the last observation date, when at least 12 months' data are available.

When extending the same ANCOVA–type I sums of square application to a multiple-factor design, a prespecified hierarchical ordering of the pooling tests^[12,18] is required. For example, when applying the two-step ANCOVA model, i.e., testing first slopes then intercepts to a study designed with two factors (e.g., strength and container size) and multiple batches, the ANCOVA model with all factors and interactions can be represented by

$$\begin{aligned} Y_{spbt} = & \alpha + \alpha_s + \alpha_p + \alpha_b + \alpha_{sb} + \alpha_{sp} + \alpha_{pb} \\ & + \alpha_{spb} + \beta t + \beta_s t + \beta_p t + \beta_b t + \beta_{sb} t \\ & + \beta_{sp} t + \beta_{pb} t + \beta_{spb} t + \varepsilon_{spbt} \end{aligned} \quad (5)$$

where subscript $s = 1, \dots, S$ represents the level of strength, $p = 1, \dots, P$ represents the level of container size, and $b = 1, \dots, B$ represents the batch number. The α s represent

the intercept coefficients, the β s represent the slope coefficients of the regression lines, ε_{spbt} represents the iid random error term that follows a standard normal distribution with mean zero and variance σ^2 .

A hierarchical ordering of null hypotheses of the pooling tests may be given as follows:

1. $H_0: \beta_{spb} = 0$, strength-by-container size-by-batch interaction for slope.
2. $H_0: \alpha_{spb} = 0$, strength-by-container size-by-batch interaction for intercept.
3. $H_0: \beta_{sb} = 0$, strength-by-batch interaction for slope.
4. $H_0: \alpha_{sb} = 0$, strength-by-batch interaction for intercept.
5. $H_0: \beta_{pb} = 0$, container size-by-batch interaction for slope.
6. $H_0: \alpha_{pb} = 0$, container size-by-batch interaction for intercept.
7. $H_0: \beta_{sp} = 0$, strength-by-container size interaction for slope.
8. $H_0: \alpha_{sp} = 0$, strength-by-container size interaction for intercept.
9. $H_0: \beta_b = 0$, batch slope.
10. $H_0: \alpha_b = 0$, batch intercept.
11. $H_0: \beta_s = 0$, strength slope.
12. $H_0: \alpha_s = 0$, strength intercept.
13. $H_0: \beta_p = 0$, container size slope.
14. $H_0: \alpha_p = 0$, container size intercept.

When using type I Sum of Squares (SS), the F -test for each factor or interaction is based on the sums of squares adjusted for the factors and interactions following it in the ordering. The process of the pooling test stops whenever a significant F -value is encountered. For example, if $H_0: \alpha_{pb} = 0$ is rejected. The final model is

$$Y_{spbt} = \alpha + \alpha_s + \alpha_p + \alpha_b + \alpha_{sp} + \alpha_{pb} + \beta t + \beta_s t + \beta_p t + \beta_b t + \beta_{sp} t + \beta_{pb} t + \varepsilon_{spbt} \quad (6)$$

even if both β_{sp} and α_{sp} are not significantly different from 0.

Hierarchical ordering of the pooling test involving batch, strength, and container size is not unique. There are six possible ordering arrangements to test for β_{sb} , β_{sp} , β_{pb} and six arrangements to test for β_b , β_p , and β_s leading to as many as 36 different test orderings for analysis. Because of the “sudden death” nature of the one-step model selection, any of the alternative arrangements may lead to a different shelf life for the product.

Alternatively, Tsong, Chen, and Chen^[18] proposed to use a more flexible stepwise modeling procedures with type III sums of squares under some proper restrictions on the order of the pooling tests. This approach will accommodate the possibility of eliminating any term within the limitation of exchangeable ordering.

To illustrate, consider the following model,

$$Y_{spbt} = \alpha + \alpha_s + \alpha_p + \alpha_b + \alpha_{sb} + \alpha_{sp} + \alpha_{pb} + \beta t + \beta_s t + \beta_p t + \beta_b t + \beta_{sb} t + \beta_{sp} t + \beta_{pb} t + \varepsilon_{spbt}$$

after eliminating the nonsignificant three-way interaction terms after pooling tests.

The F -statistics for testing $\beta_{sb} = 0$, $\beta_{sp} = 0$, and $\beta_{pb} = 0$ are calculated using type III SS, $R(\beta_{sb} | \alpha, \alpha_s, \alpha_p, \alpha_b, \alpha_{sb}, \alpha_{sp}, \alpha_{pb}, \beta, \beta_s, \beta_p, \beta_b, \beta_{sp}, \beta_{pb})$, $R(\beta_{sp} | \alpha, \alpha_s, \alpha_p, \alpha_b, \alpha_{sb}, \alpha_{sp}, \alpha_{pb}, \beta, \beta_s, \beta_p, \beta_b, \beta_{sb}, \beta_{pb})$, and $R(\beta_{pb} | \alpha, \alpha_s, \alpha_p, \alpha_b, \alpha_{sb}, \alpha_{sp}, \alpha_{pb}, \beta, \beta_s, \beta_p, \beta_b, \beta_{sp}, \beta_{sb})$, respectively. The term with the largest nonsignificant p -value (say β_{sb}) is to be eliminated from the model. Then, in the reduced model

$$Y_{spbt} = \alpha + \alpha_s + \alpha_p + \alpha_b + \alpha_{sb} + \alpha_{sp} + \alpha_{pb} + \beta t + \beta_s t + \beta_p t + \beta_b t + \beta_{sp} t + \beta_{pb} t + \varepsilon_{spbt}$$

α_{sb} , the corresponding intercept term, is tested for poolability. It is eliminated from the model if the F -value using $R(\alpha_{sb} | \alpha, \alpha_s, \alpha_p, \alpha_b, \alpha_{sp}, \alpha_{pb}, \beta, \beta_s, \beta_p, \beta_b, \beta_{sp}, \beta_{pb})$ for testing $H_0: \alpha_{sb} = 0$ is not significant. In this case, the model is further reduced to

$$Y_{spbt} = \alpha + \alpha_s + \alpha_p + \alpha_b + \alpha_{sp} + \alpha_{pb} + \beta t + \beta_s t + \beta_p t + \beta_b t + \beta_{sp} t + \beta_{pb} t + \varepsilon_{spbt}$$

Otherwise, if α_{sb} is not equal to zero, it will be retained in the model. Based upon the above further reduced model, the next term to be eliminated is either β_{sp} or β_{pb} depending on which has the larger nonsignificant p -value calculated by $R(\beta_{sp} | \alpha, \alpha_s, \alpha_p, \alpha_b, \alpha_{sp}, \alpha_{pb}, \beta, \beta_s, \beta_p, \beta_b, \beta_{pb})$ and $R(\beta_{pb} | \alpha, \alpha_s, \alpha_p, \alpha_b, \alpha_{sp}, \alpha_{pb}, \beta, \beta_s, \beta_p, \beta_b, \beta_{sb})$, respectively. Depending on the testing results of β_{sp} and β_{pb} , the model may be even further reduced to one of the following two:

$$Y_{spbt} = \alpha + \alpha_s + \alpha_p + \alpha_b + \alpha_{sp} + \alpha_{pb} + \beta t + \beta_s t + \beta_p t + \beta_b t + \beta_{pb} t + \varepsilon_{spbt}$$

$$Y_{spbt} = \alpha + \alpha_s + \alpha_p + \alpha_b + \alpha_{sp} + \alpha_{pb} + \beta t + \beta_s t + \beta_p t + \beta_b t + \beta_{sp} t + \varepsilon_{spbt}$$

The stepwise modeling process stops when no further term can be eliminated.

There are two restrictions to the testing orders.

1. Test higher-level interaction terms before lower-level interactions or main factors. However, the lower-level interactions or main design factors can be tested even with significant higher-level interaction terms, as long as there are no common design factors involved.
2. For each factor or interaction, test the equality of slope before testing the equality of the corresponding intercept. In addition, no equality of intercept is tested if the equality of the corresponding slope has been rejected.

At the premarketing stage when the sample size (i.e., number of observation times) is small, the major concern with the pooling test is its power to reject the null hypothesis.^[1–3,13–16] In order to reduce the rate of false pooling, a significance level of 0.25 was recommended for testing for pooling batches in simple stability designs.^[13–16] Fairweather, Lin, and Kelly^[19] proposed to use large significance level such as $\alpha = 0.25$ for all testing that involves the batch term and $\alpha = 0.05$ for any other pooling test. These significance levels are currently recommended in *ICH Guidance*.^[10] Note that Fairweather, Lin, and Kelly^[19] used the error rate for the *F*-tests based on type I sums of squares instead of the *F*-tests based on type III sums of squares as proposed by Tsong, Chen, and Chen.^[18]

DISCUSSION AND CONCLUSIONS

The ANCOVA approach has been the conventional and standard tool to analyze stability study data. With appropriate significance levels set for the intercept and slope pooling tests, decision on pooling data of different batches or across design factors can be made for the determination of the shelf lives. The extension of the conventional modeling with *F*-test based on type I sums of squares for pooling to multifactorial designs, including both complete and fractional, has some unwanted limitations. The alternative approach with ANCOVA stepwise modeling using *F*-tests based on type III sums of squares for pooling tests may eliminate these difficulties. Alternative approaches, such as pooling by equivalence assessment in order to replace pooling tests of low power, are topics of great interest to nonclinical statisticians.^[20] Random effect models for shelf life prediction has also been proposed in the literature.^[21–25] The supporting argument of such an approach is that the shelf life is determined for future batches rather than for the few batches studied. However, in practice, the batches at the NDA stage are not a random sample and their number is often too small to permit a variance estimate with precision.

ACKNOWLEDGMENT

This manuscript was prepared with the support of Regulatory Science Research Grant RSR02-015 of the Center of Drug Evaluation and Research, U.S. FDA. The authors wish to thank the FDA CDER Office of Biostatistics Stability Working Group for the support and discussion on the development of this manuscript.

Abstract

Assays are utilized in the pharmaceutical industry to characterize drugs and biological products. Assay development is coordinated with pharmaceutical development to furnish the tools necessary to guide the research process. This entry will discuss the varieties of technologies and statistical methodologies used in the development of an assay.

INTRODUCTION

Assays are utilized in the pharmaceutical industry to characterize drugs and biological products. Assay development is coordinated with pharmaceutical development to furnish the tools necessary to guide the research process. Measures of content, potency, and purity are combined to warrant the safety and effectiveness of marketed products. Thus special care is taken to develop assays that are sensitive to changes in the important properties of pharmaceutical products.

Statistics plays a primary role in the processing of assay results and in the development of experimental strategies to optimize an analytical method. Most of these strategies employ basic statistical moieties, and they are thus accessible to the analytical researcher and biostatistician alike. Their simplicity does not absolve the user, however, from careful attention to their implementation and interpretation.

This entry will discuss the varieties of technologies and statistical methodologies used in the development of an assay. A review of standard calibration methodologies will illustrate the synergy between the scientific and statistical properties of an assay. Sound statistical experimental design can be utilized to explore the effect of operational factors on assay response and to establish the levels of the factors that yield reliable results.

TERMINOLOGY

Several features common to all assays performed in pharmaceutical research, development, and quality control are associated with specific terminology. These terms will be defined here and illustrated with specific cases.

The *analyte* is the substance being measured. This may be the active drug in the product or that compound in clinical samples obtained during clinical development. The analyte can also be a known impurity or a degradate of the active chemical species. Biotechnological and biological

products are subject to the introduction of adventitious agents, such as retroviruses associated with the biological system used to produce the product. In vaccine studies, products of the biological response of the vaccinee, such as antibodies or responder cells, are measured to establish successful immunization with the immunogen.

The *sample matrix* is the environment in which the analyte exists. For a drug product, this will be the inactive excipients that comprise the formulation, while for a biological it will be these as well as byproducts of the process, such as cellular debris, surfactants, and other process components. The clinical sample is the matrix for specimens tested from pharmacokinetic studies as well as from immunogenicity studies.

Various terms are used to describe the units of measure of an assay. Most assays of a drug substance measure the *content* or *gravimetric mass* of the compound, which is reported in units of mass (e.g., micrograms) or mass per volume of sample (e.g., micrograms per milliliter). The *potency* of a drug represents the biological activity of the compound, and it is usually reported as the amount of the analyte that induces a specific response (e.g., the amount of a vaccine that is effective in inducing antibody response in half of immunized animals is called the 50% effective dose, or ED_{50}). Many potency assays involve a titration of a drug or biological (i.e., a series of doses of the analyte), yielding a *titer* for the sample. Finally, many assays measure the physical properties of a drug or biological, such as pH, polydispersity, and solubility.

The term *assay* is used synonymously to represent the particular analytical method, an individual run of the procedure, or the composite result obtained for a sample in multiple runs of the procedure. Where not otherwise specified in this and related entries, the term *assay* will refer to the analytical method being discussed.

In this entry, a calibration *standard* represents the material in an assay, which is utilized to construct the “ruler” against which test samples are measured, while an assay *control* is a material that is measured alongside test

samples and that is used to monitor the performance of the procedure.

ASSAY TECHNOLOGIES

A variety of technologies form the foundation of analytical method development. A basic understanding of the mechanism and operation of these technologies is useful to their successful implementation.

Separation techniques, such as high-performance liquid chromatography (HPLC), are among the most widely employed assay technologies in the pharmaceutical industry. The basis of HPLC is the separation of molecular species, which are forced by a mobile phase through a resin-packed column (solid phase) under fixed pressure. The separation can be used on different properties of the analyte, including size, ionization, hydrophobicity, and affinity to a ligand. The output from an HPLC assay is a chromatographic trace, displaying spiked peaks with areas that are directly proportional to the amount of each molecular species in the sample. High-performance liquid chromatography is used either to detect or to quantify the amount of an analyte in a product or clinical sample. Quantitation of the analyte is usually accomplished using standard calibration techniques, in correspondence to a reference preparation.

Immunoassays employ the principle of antibody–antigen binding as a means to quantify an analyte. There are a variety of technologies associated with immunoassay, but common to all of these is a *detector*. Among the most common detectors are radioactive isotopes (associated with radioimmunoassay, or RIA), which discharge radioactive emissions in counts per minute (CPM), and enzyme substrates (associated with enzyme immunoassay, or EIA), which yield a change in the optical density (OD) of the solution at a specific wavelength of light. In either case, the level of detector signal is directly proportional to the amount of analyte in the sample. As in HPLC, quantitation of the analyte is accomplished using standard calibration techniques in correspondence to a reference preparation.

Many pharmacologically active compounds yield a response in vivo, in a biological milieu. Activity can be tested in a specified tissue, in cell culture, or in animals, utilizing biological assay techniques. A typical *bioassay* in animals is comprised of groups of animals, with each group receiving a graded dose of the test compound. The number of animals eliciting a particular response in each group is noted, and an endpoint is calculated from the dose series using one of a variety of quantal calculation methods.

A number of emerging technologies have been introduced into the analytical portfolio of many drugs and vaccines. In most cases these technologies fit into the traditional analytical paradigm. Thus fluorescence and refractory index can now easily be measured in a sample, which serve as the detector in a traditional calibration

assay design. Powerful methods for exploring the structure of a drug molecule or biological derivative, such as nuclear magnetic resonance (NMR) and polymerase chain reaction (PCR), bring with them new challenges for assay development and validation.

CALIBRATION

The most common assay design used to quantify the amount or potency of analyte in a drug or clinical sample is a standard curve, or calibration, design. A typical run of a calibration assay is comprised of a series of known amounts of a calibration, or reference, standard, run alongside one or several levels of a test preparation. The responses from the standard series are statistically fit using one of a variety of mathematical equations; this fit is then used to predict the amount of the analyte in the test sample. A typical calibration assay is illustrated in Fig. 1.

Linear Calibration

One of several strategies can be employed in selecting an appropriate calibration equation for an assay. During development, data from several runs of the standard preparation can be used to identify the “linear” range of the standard curve, in order to utilize a linear equation to fit the standard curve. This range is usually determined graphically, and can be verified statistically using common goodness-of-fit techniques. Some of the factors related to the implementation of the linear standard curve design include (1) the range of concentrations used in the standard curve; (2) the number of standard curve concentrations; and (3) the concentration scaling—i.e., arithmetic (e.g., 10, 20, 30, 40, etc.) or geometric (e.g., 10, 20, 40, 80, etc.).

These factors will, for the most part, be selected on the basis of the intended use and specific characteristics of the assay. The range of the standard curve should embrace the expected range of concentrations in test samples, with the exception that high-concentration samples can usually be manipulated (either by dilution or by loading

Fig. 1 Calibration using a linear fit to a standard curve; inverse regression is employed to predict the concentration corresponding to the response in an unknown

a different amount of the test specimen) to achieve a level that falls within the standard curve range. The number of standard curve concentrations can be selected on the basis of the impact on the margin of error of measurement of the analyte concentration in the test sample. The concentration scaling can be selected on the basis of the behavior in the variability of the instrument readout (e.g., CPM, OD); if the variability of the readout is well behaved (i.e., there is no association between variability and response level), then an arithmetic scaling of standard curve concentrations can be used. If the variability of the instrument readout increases with increased response, a geometric scaling of response may be preferred. In this case, the standard curve equation should be fit using a log-log transformation of the data, thereby achieving both equal spacing among the standard curve concentrations and homogeneity of variability across the (log) responses. A linear-linear fit and a log-log fit to a standard curve with geometric scaling are illustrated in Fig. 2.

Once a linear equation has been fit to the standard curve data, and prior to predicting the concentrations in unknowns, the statistical “goodness of fit” of the linear equation can be assessed using common regression diagnostics. Customarily, a restriction is placed upon the coefficient of determination (R^2) associated with the regression fit, and an assay run that fails to meet this restriction is judged invalid and is usually repeated. This criterion is frequently and inappropriately used to select the linear range of the standard curve during development of an assay as well as during its routine use. The dangers of relying exclusively on R^2 as a measure of goodness of fit are illustrated in an article by Anscombe.^[1] Several conditions yielding satisfactory R^2 values, such as nonlinear standard curve kinetics, a regression outlier, or heterogeneity of variability across the range of the standard curve, might still require remedial action. These conditions might more aptly be addressed through graphical diagnostic techniques, such as residual plots. Fig. 3 illustrates residual patterns associated with a properly behaved regression fit, along with several commonly

occurring alternatives. Residual plots can, in turn, be supplemented with more sophisticated diagnostic criteria, such as statistical tests of patterned residuals, of curvature, or of regression outliers.^[2]

Another graphical device used to diagnose the linearity of the standard curve is a “response factor” plot.^[3] The “response factor” is calculated as the ratio of the instrument readout to the nominal concentration of each standard curve point, and it is plotted against concentration. When the regression intercept is zero, the “response factor” corresponds to the slope of the standard curve, and it should be constant across levels. If a trend is observed, this indicates either a nonlinear calibration curve or a nonzero intercept. For more complex calibration functions, or when a nonzero intercept can be tolerated, the “response factor” plot of the standard can be compared with that of a concentration series of a test sample; similarly shaped “response factor” profiles indicate an assay that is “linear,” in the sense that measurements at each level of the test sample will be directly proportional to the test sample concentrations (see “Linearity” in the entry *Assay Validation*).

Having established goodness of fit of the standard curve, parameter estimates for the intercept (a) and the slope (b) can be utilized to predict the concentration of analyte in an unknown sample:

$$\hat{X} = \frac{Y_{\text{unknown}} - a}{b}$$

where Y_{unknown} represents the response in the unknown (note that this pertains to the case of a “linear-linear” fit to the standard curve; prediction from a “log-log” fit of the standard curve can be developed similarly). The reliability of the estimate can be ascertained through the prediction interval on the result:^[4]

$$\frac{\hat{X} \pm \frac{t_{n-2} \cdot \hat{\sigma}}{b} \sqrt{(1 + 1/n) \cdot (1 - g) + \hat{X}^2 / SXX}}{1 - g}$$

Fig. 2 A linear-linear fit to a geometrically scaled standard curve alongside a log-log fit, illustrating equal spacing between log concentrations

Fig. 3 Residual plots for standard curve fits exhibiting various behaviors: (a) normal behavior with random variability, (b) nonlinear kinetics, (c) a regression outlier, and (d) heterogeneity of variance

where

$$g = \frac{t_{n-2}^2}{t_b^2} = \frac{t_{n-2}^2 \cdot \hat{\sigma}^2}{b^2 \cdot SXX}$$

t_{n-2} is the appropriate percentile from the t -distribution with $n - 2$ degrees of freedom, $\hat{\sigma}$ is the standard error of the regression, t_b is the statistic associated with a test of significance of the regression slope, and SXX is the sum of squared deviations in the concentrations. In most cases, g will be small, and can be treated as if it were equal to “0” in the calculation of the standard error of estimate of the predicted concentration. In this case, the standard error can be utilized in conjunction with the predicted concentration to calculate the relative standard deviation (RSD) of the result:

$$\text{RSD} = 100 \cdot \frac{\frac{\hat{\sigma}}{b} \cdot \sqrt{1 + 1/n + \hat{X}^2/SXX}}{\hat{X}} \%$$

In this way, the variability of each prediction can be determined, and results that meet a prespecified restriction (e.g., $\leq 20\%$ RSD) can be reported.

Nonlinear Calibration

Many analytical methodologies, primarily immunoassays, generate nonlinear standard curves. As indicated earlier, the linear range of the standard curve can be identified, and linear calibration can be used to fit the standard curve and interpolate sample results. This portion of the standard curve is only approximately linear, however, and it might be more suitable to fit the entire curve using one of a variety of concentration kinetics equations. In fact, basic immunochemistry principles predict that the standard curve can be modeled using the four-parameter logistic regression equation (Fig. 4). Letting Y be the instrument readout associated with an individual standard curve concentration X , the four-parameter logistic equation is as follows:

$$Y = D + \frac{A - D}{1 + \left(\frac{X}{C}\right)^B}$$

In this equation, the parameter D represents the minimum response (usually the background), while A represents the level in response associated with the saturation of the

Fig. 4 Illustration of a standard curve fit using four-parameter logistic regression; inverse prediction is utilized to estimate the concentration corresponding to the response in an unknown

“binder.”^[5] The parameters B and C are related to the slope and intercept from the linear regression of logistic transformed response on log concentration. In fact, C corresponds specifically to EC_{50} , the concentration of the standard predicted to yield 50% activity in the assay. This parameter can be used to monitor the stability of the standard.

The nonlinear equation can be fit using conventional nonlinear curve-fitting methodology. Similar regression diagnostics as employed with linear calibration can be utilized in conjunction with nonlinear regression (e.g., residuals plots, regression outliers), while the interpolated concentration for an unknown sample can be supplemented by its standard error, yielding an assessment of the quantifiable range for an individual assay run:

$$\hat{X} = C \cdot \left[\frac{A - Y}{Y - D} \right]^{1/B}$$

The standard error of a predicted value can be established via estimates of the variances and covariances of the parameter estimates, and measurement variability, using a first-order Taylor series approximation:^[6]

$$\text{var}(\hat{X}) = \sum \left(\frac{\partial \hat{X}}{\partial P} \right)^2 \cdot \text{var}(P) + \sum \sum \left(\frac{\partial \hat{X}}{\partial P} \right) \left(\frac{\partial \hat{X}}{\partial Q} \right) \cdot \text{cov}(P, Q) + \left(\frac{\partial \hat{X}}{\partial Y} \right)^2 \cdot \hat{\sigma}^2$$

where $\hat{X}$ is the predicted concentration, P and Q are parameters of the nonlinear model, and $\text{var}(P)$ and $\text{cov}(P, Q)$ represent the approximate variances and covariances among the parameters.

The design of an assay utilizing a nonlinear standard curve will differ from that of a linear calibration system in several ways. Typically more standard concentrations will be necessary to support the estimation of additional parameters in the nonlinear model. Immunoassay design

usually requires that standard curve points be extended to measure the asymptotes of the curve (A and D in the four-parameter logistic model). A common concern is that this implies that test samples can be read from these “flat” portions of the standard curve; however, the reliable portion of the standard curve can be calculated for each run using methods discussed previously for calculating the standard error of a predicted concentration from the nonlinear curve fit.

Other Calibration Conventions

One means to ameliorate the effects of increasing variability with increasing response is to transform the data. Commonly used transformations are the log and square root. Another widely used solution is to implement a weighted regression, where the weight assigned to each standard curve concentration is a function of the predicted response. This method is called *iteratively reweighted least squares*;^[7] it can easily be implemented with computation software such as EXCEL®.

The weighting functions of the predicted response (y) that are commonly used are (1) weight = $1/y$, when the response is believed to be generated by a Poisson process (e.g., when the response is a count, such as in RIAs; note that this is analogous to performing a square root transformation of the instrument readout); and (2) weight = $1/y^2$, when it can be established that the %RSD is a constant (note that this is analogous to performing a log transformation of the instrument readout).

An adaptation of the standard calibration method is a parallel-line design. In the parallel-line design, a test sample is diluted in conjunction with the standard preparation, forming simultaneous dose–response curves. Statistical conformance to the assumptions of the parallel-line model is tested prior to the measurement of the *relative potency* (RP) of the test preparation to the standard. The assumptions tested are specific to the mathematical model utilized to fit the simultaneous dose–response profiles. When a simple linear model is used to fit the data, tests of linearity and parallelism of the dose–response curves usually precede potency estimation.^[8] The measured relative potency corresponds to the horizontal distance between parallel response profiles, at any level of response; thus, when the response profiles are parallel, this horizontal distance is the same at all levels of response. When the response profiles are not parallel, the estimated relative potency (horizontal distance) is not unique and can vary depending upon the level of response used to predict the relative potency (see Fig. 5).

The four-parameter logistic regression equation is frequently used to model response in a parallel-line immunoassay. The goodness of fit of various parameterizations of the simultaneous four-parameter logistic equation can be tested, preliminary to estimating the relative potency.^[5]

Fig. 5 The relative potency represents the horizontal distance between dose–response profiles. The relative potency is unique when the profiles are parallel, but it is different for different levels of response when the profiles are not parallel

In either case, when the assumptions are met, the relative potency of the test preparation to the standard can be estimated, along with an appropriate confidence interval:

$$M = \log(\text{RP}) = \bar{x}_s - \bar{x}_t - \frac{\bar{y}_s - \bar{y}_t}{b}$$

and

$$(\bar{x}_s - \bar{x}_t) + \frac{\left[M - \bar{x}_s + \bar{x}_t \pm \frac{t_{df}}{b} \left\{ \hat{\sigma}^2 (1-g)(1/n_s + 1/n_t) + (M - \bar{x}_s + \bar{x}_t)^2 / \sum SXX \right\}^{1/2} \right]}{1-g}$$

where

$$g = \frac{t_{df}^2}{t_b^2} = \frac{t_{df}^2 \cdot \hat{\sigma}^2}{b^2 \sum SXX}$$

x represents the dose, y is the response, b is the pooled slope from the standard and test preparations, t_{df} is the appropriate percentile from the t -distribution with $n_s + n_t - 2$ degrees of freedom, $\hat{\sigma}$ is the standard error of the regression, t_b is the statistic associated with a test of significance of the pooled regression slope, and SXX is the sum of squared deviations in the concentrations, which is summed between standard and test preparations.

The relative potency is unitless and represents the “shift” in concentration of the dose–response curve for the test sample relative to the standard sample. A relative potency of test to standard equal to 1.00 represents “equipotence” of the two samples. The reported potency of the test preparation can be converted to an absolute scale by multiplying the known potency of the standard by the relative potency.

Design components of a parallel-line assay are the same as those for a calibration assay, with the additional

requirements implicit in the reliable estimation of a relative potency. Thus in addition to the choice of the dose range and the number of doses of the test and standard preparations, these should be selected so as to achieve approximately equal average responses across doses for the two preparations.

ASSAY OPTIMIZATION

Assay development commences with scientifically reasonable levels of factors that might affect the assay (factors such as pressure, pH, temperature of incubation, time of incubation, and levels of certain key reagents) and then proceeds with empirical studies that seek to optimize the levels of these factors. The goal of the optimization is to achieve satisfactory performance in one or several key attributes of the assay. Examples of performance attributes include background reactivity in an immunoassay, linearity in an HPLC, and repeatability and precision of the method (see the entry *Assay Validation*).

Key to the successful optimization of a method is a strategic plan for studying the effects of the assay factor(s). This can be accomplished using tools such as factorial and fractional-factorial experimental designs.^[9] Consider an example in which an experiment is conducted to minimize the background in an immunoassay. The factors that are thought to influence background reactivity (Y in optical density, OD) are incubation temperature ($X1$, ranging from 30°C to 35°C), incubation time ($X2$, ranging from 6 to 8 hr), and dilution of conjugate ($X3$, ranging from

Table 1 A 2³ Factorial Experiment Studying the Effects of Temperature, Time, and Dilution of Conjugate on Background Level in an EIA

Run	Temperature (X1)	Time (X2)	Dilution (X3)	OD
1	30°C	6 hr	1:1000	0.29
2	30°C	6 hr	1:4000	0.16
3	30°C	8 hr	1:1000	0.34
4	30°C	8 hr	1:4000	0.22
5	35°C	6 hr	1:1000	0.30
6	35°C	6 hr	1:4000	0.19
7	35°C	8 hr	1:1000	0.35
8	35°C	8 hr	1:4000	0.20

Runs are usually performed in randomized order.

1:1000 to 1:4000). A 2³ factorial design is used to study simultaneously the effects of these three factors in Table 1. By inspection, it appears that conjugate dilution (X3) has an effect on background reactivity, with the 1:1000 dilution yielding a higher background than the 1:4000 dilution. The effect of dilution of conjugate can be estimated from experimental results:

$$X3 = \frac{0.29 + 0.34 + 0.30 + 0.35}{4} - \frac{0.16 + 0.22 + 0.19 + 0.20}{4} = 0.32 - 0.19 = 0.13$$

The interaction between factors can also be estimated; for example, the interaction of temperature with dilution of conjugate (X1* X3) is:

$$X1 * X3 = \frac{0.29 + 0.34 + 0.19 + 0.20}{4} - \frac{0.16 + 0.22 + 0.30 + 0.35}{4} = 0.255 - 0.2575 = -0.0025$$

The effects of these factors and their interactions can be plotted in order of largest to smallest absolute effect in a Pareto plot,^[9] as shown in Fig. 6. This plot shows that dilution of conjugate (X3) asserts the greatest effect on background OD, while incubation time (X2) has the next largest effect. Temperature of incubation (X1) and the two- and three-factor interactions appear to have little affect.

Another aspect of assay optimization is the replication strategy used to test a sample. This is discussed in the entry *Assay Validation*.

Fig. 6 Pareto plot showing absolute effects of temperature (X1), time (X2), and dilution of conjugate (X3) on background reactivity in an immunoassay

BIOLOGICAL ASSAYS AND ASSAYS OF ANALYTES IN COMPLEX MATRICES

Many biologicals and some drugs are tested using biological assays (bioassays), which measure the biological activity of the analyte. This is typically true of vaccines, which induce an antibody response in animals as well as in man. In a bioassay for a vaccine, a fixed number of mice (or some other animal species that responds to the vaccine; vaccines are also tested ex vivo, in tissue cells that demonstrate a prescribed response, usually cytopathicity due to infection with a vaccine virus) are injected, each with one of a graded series of doses of the vaccine. After a prescribed period of time, the mice are bled and the presence or absence of antibody is determined in each animal. The data become a series of response rates across doses. Assays of this sort are often called “quantal response” assays. A typical quantal response curve is illustrated in Fig. 7. The reported potency is usually either the dose predicted to yield responses in 50% of immunized animals (usually called either the ED₅₀ in an in vivo animal model or TCID₅₀ when tissue culture infection is the analytical

Fig. 7 Quantal response curve fit using probit analysis; the estimated ED₅₀ represents the level of the test preparation that is predicted to yield 50% response in animals

endpoint) or the relative potency of the test preparation to a standard (this will be mathematically equal to the ratio of ED_{50} 's).

There are several ways to calculate these endpoints, among them methods due to Reed and Muench^[10] and to Spearman and Kärber, as well as probit and logit analyses. The Reed and Muench method is easy to table and was popular before computers were enlisted to perform the complex calculations associated with other methods of analysis. It does not provide, however, any confirmation of the reliability of the measured potency. The Spearman and Kärber method furnishes an estimate of the standard error of the estimate; the probit method offers this along with a test of goodness of fit of the probit model.

Several design factors affect the statistical properties of an in vivo assay. The number of doses, the dose range, and the number of animals or tissue culture wells per dose affect the variability of the measured potency. Care should be taken in defining the cutoff when an immunoassay is used to score positive responders. A cutoff that yields a high "false-negative" rate in the immunoassay will result in a potency that is negatively biased. A parallel-quantal-response design can be used to ameliorate the affects of the operating characteristics of the immunoassay. As with parallel-line design in immunoassay, this requires that the quantal response curves be "parallel," and it results in the measurement of a relative potency of the test to the standard.

CONCLUSION

Assays are used to characterize the content and properties of pharmaceutical products and vaccines. Careful development of these methods helps ensure the consistency, safety, and effectiveness of products for human and animal

use. Statistical considerations during the development of an assay include the analytical method design, the processing algorithm, and optimization strategies such as multifactor design of experiments. Due consideration should also be given to the variability of the analytical measurement, in assessing its value as a descriptor of the analytical property of interest. Development is complete when all important processing parameters have been identified and acknowledged in a standard operating procedure for the method. Only when development is complete should assay validation commence, and the method be put into routine use in conjunction with adequate assay quality control.

Assay Validation

Timothy L. Schofield

Merck Research Laboratories, West Point, Pennsylvania, U.S.A.

Abstract

Upon completion of the development of an assay, and prior to implementation, a well-conceived assay validation is carried out to demonstrate that the procedure is fit for use. This entry will introduce the validation parameters used to describe the characteristics of an analytical method.

INTRODUCTION

Upon completion of the development of an assay, and prior to implementation, a well-conceived assay validation is carried out to demonstrate that the procedure is *fit for use*. Regulatory requirements specify the assay characteristics that are subject to validation and suggest experimental strategies to study these properties. These requirements, when united with sound statistical experimental design, furnish an effective and efficient validation plan. That plan should also address the form of statistical processing of the experimental results and thereby ensure reliable and meaningful measures of the properties of the method.

This entry will introduce the validation parameters used to describe the characteristics of an analytical method. Performance metrics associated with those parameters will be defined, with illustrations of their utility in application. Realistic and relevant acceptance criteria are proposed, as a basis for evaluating a procedure. An example of a validation protocol will illustrate the design of a comprehensive exploration, in conjunction with the statistical methods used to extract the relevant information.

TERMINOLOGY

Most of the terminology related to assay validation can be found in the entry on *Assay Development*. Some terms that are unique to this topic are *relative standard deviation*, *spike recovery*, and *dilution effect*.

The relative standard deviation (RSD) is a measure of the proportional variability of an assay and is usually expressed as a percentage of the measured value:

$$\text{RSD} = 100 \times \frac{\hat{\sigma}_{\text{assay}}}{\hat{x}} \%$$

Note that the RSD is the same as the coefficient of variation in statistics. Other conventions for calculating the RSD, which are appropriate for measurements that are

lognormally distributed, utilize $\hat{\sigma}_{\log \hat{x}}$, the log standard deviation or the fold variability:

$$\begin{aligned} \text{RSD} &= 100 \hat{\sigma}_{\log \hat{x}} \% \\ \text{or RSD} &= 100(\text{FV} - 1)\% = 100(e^{\hat{\sigma}_{\log \hat{x}}} - 1)\% \end{aligned}$$

Note that the log standard deviation provides an approximation to the RSD; it should be restricted to levels below 20% RSD. An important feature of the RSD is that it is calculated from the predicted measurements for a sample, such as concentrations, and not from an intermediate, such as the instrument readout. These are the same only in the case of linear calibration.

Spike recovery is the process of measuring an analyte that has been distributed as a known amount into the sample matrix, with results usually reported as percent recovery or percent bias. Dilution effect is a measure of the proportional bias measured across a dilution series of a validation sample; it is usually reported as percent bias per dilution increment (usually percent bias per twofold dilution).

REGULATORY REQUIREMENTS

The U.S. Pharmacopeia specifies that the “Validation of an analytical method is the process by which it is established, in laboratory studies, that the performance characteristics of the method meet the requirements for the intended analytical applications.”^[1] Key to this definition is the treatment of a validation study as an *experiment*, with the goal of that experiment being to demonstrate that the assay is fit for use. As an experiment, a validation study should be suitably designed to meet its goal, while the acceptance criteria should yield opportunities to judge the assay as unsuitable as well as suitable, possibly requiring further development. This does not suggest that it is the role of the validation study to optimize the assay; this should be completed during the assay development. In fact, the properties

of the assay are probably well understood by the time the validation experiment is undertaken. The validation experiment should serve as a “snapshot” of the long-term routine performance of the assay, thereby documenting its characteristics so that we can make reliable decisions during drug development and control.

The International Conference on Harmonization (ICH) has devoted two topics of its guidelines to analytical method validation. The first topic, entitled “Guideline on Validation of Analytical Procedures: Definitions and Terminology,”^[12] offers a list of validation parameters that should be considered when implementing a validation experiment and guidance toward the selection of those parameters. The second topic, entitled “Validation of Analytical Procedures: Methodology,”^[13] provides direction on the design and analysis of results from a validation experiment.

ASSAY VALIDATION PARAMETERS AND VALIDATION DESIGN

It is convenient for the purposes of planning a validation experiment to dichotomize assay validation parameters into two categories: parameters related to the accuracy of the analytical method and parameters related to variability. In this way, the analyst will choose the test sample set that will be carried forward into the validation, in accord with accuracy parameters, and devise a replication plan for the validation to satisfy the estimation of the variability parameters.

The validation parameters related to the accuracy of an analytical method are accuracy, linearity, and specificity. The *accuracy* of an analytical method “expresses the closeness of agreement between the value which is accepted either as a conventional value or an accepted reference value, and the value found.” Accuracy is usually established by spiking known quantities of analyte (see the entry *Assay Development* for definitions of terms) into the sample matrix and demonstrating that these can be completely recovered. Conventional practice is to spike using five levels of the analyte: 50%, 75%, 100%, 125%, and 150% of the declared content of analyte in the drug (note that this is more stringent than the ICH, which requires “a minimum of nine determinations over a minimum of three concentration levels”). The experimenter is not restricted to these levels but should plan to spike through a region that embraces the range of expected measurements from samples that will be tested during development and manufacture. Accuracy can also be determined relative to a “referee” method; in the case of complex mixtures, such as combination vaccines, accuracy can be judged relative to a monovalent control.

The *linearity* of an analytical procedure is “its ability (within a given range) to obtain test results that are directly proportional to the concentration (amount) of analyte in the sample.” This parameter is often confused with the

“graphical linearity” of the standard curve; in fact, the guidelines encourage the experimenter to evaluate linearity “by visual inspection of a plot of signals as a function of concentration or content.” The principle of analytical linearity, however, should not be confused with an abstract property, such as the “straightness of the standard curve,” but rather should be based upon the attribute that graded concentrations of the analyte yield measurements that are in proper proportion. Thus, for example, if a sample is tested in twofold dilution, the measured concentrations in those samples should yield a twofold series. In this way, linearity can be established from the spiking experiment outlined earlier, while a dilution series is usually employed when the assessment of linearity cannot be achieved through spiking (i.e., when the purified analyte does not exist, such as in vaccines).

Specificity is “the ability to assess unequivocally the analyte in the presence of components which may be present.” Thus specificity speaks to the variety of sample matrices containing the analyte, including process intermediates and stability samples. The ICH guidelines provide a comprehensive description of the means to establish specificity in identity tests and in analytical methods for impurities and content. When the samples are available, specificity can be established through testing of the analyte-free matrix.

The assay validation parameters related to variability are precision, repeatability, ruggedness, limit of detection, and limit of quantitation. The *precision* of an assay “expresses the closeness of agreement (degree of scatter) between a series of measurements obtained from multiple sampling of the same homogeneous sample under the prescribed conditions.” Precision is frequently called “interrun” variability, where a run of an assay represents the independent preparation of assay reagents, tests samples, and a standard curve. The *repeatability* of an assay “expresses the precision under the same operating conditions over a short interval of time,” and is frequently called “intrarun” variability. Repeatability and precision can be studied simultaneously, using the levels of a sample required to establish accuracy and linearity, in a consolidated validation study design such as that depicted in Table 1. Here precision is associated with the multiple experimental runs, while repeatability is associated with the run-by-level interaction. In many cases, the experimenter may wish to test true within-run replicates rather than employ this subtle statistical artifact. The runs in this design can be strategically

Table 1 Strategic Validation Design Employing Five Levels of the Analyte Tested in k Independent Runs of the Assay

Run	Level				
	1	2	3	4	5
1	y_{11}	y_{12}	y_{13}	y_{14}	y_{15}
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
n	y_{n1}	y_{n2}	y_{n3}	y_{n4}	y_{n5}

allocated to *ruggedness* parameters, such as laboratories, operators, and reagent lots, using a combination of nested and factorial experimental design strategies. Thus *operators* might be nested within *laboratory*, while *reagent lot* can be crossed with *operator*.

The *robustness* of an analytical method “is a measure of its capacity to remain unaffected by small, but deliberate, variations in method parameters,” and might be more suitably established during the development of the assay (see the entry on *Assay Development*). Note that while ruggedness parameters represent uncontrollable factors affecting the analytical method, robustness parameters can be varied and should be controlled when it has been observed that they have an effect on assay measurement.

The *limit of detection* (LOD) and *limit of quantitation* (LOQ) of an assay can be obtained from replication of the standard curve during the implementation of the consolidated validation experiment. The LOD of an analytical procedure “is the lowest amount of analyte in a sample that can be detected but not necessarily quantitated as an exact value,” while the LOQ “is the lowest amount of analyte in a sample that can be quantitatively determined with suitable precision and accuracy.” The limit of quantitation need not be restricted to a lower bound on the assay, but might be extended to an upper bound of a standard curve, where the fit becomes flat (for example, when using a four-parameter logistic regression equation to fit the standard curve).

Finally, the composite of the ranges identified with acceptable accuracy and precision is called the *range* of the assay.

CHOICE OF VALIDATION PARAMETERS

The choice of parameters that will be explored during an assay validation is determined by the intended use as well as by the practical nature of the analytical method. For example, a biochemical assay using a standard curve to establish drug content might require the exploration of all of these parameters if the assay is to be used to determine low as well as high levels of the analyte (such as an assay used to determine drug level in clinical samples or an assay that will be used to measure the content of an unstable analyte). If the assay is used, however, to determine content in a stable preparation, the LOD and LOQ need not be established. On the other hand, an assay for an impurity requires adequate sensitivity to detect and/or quantify the analyte; thus the LOD and LOQ become the primary focus of the validation of an impurity assay.

Many of these assay validation parameters have limited meaning in the context of biological assay and various other potency assays. There is no means to explore the accuracy and linearity of assays in animals or tissue culture, where the scale of the assay is defined by the assay; thus validation experiments for this sort of analytical method are usually restricted to a study of the specificity and ruggedness

of the procedure. As discussed previously, the accuracy of a potency assay may be limited to establishing linearity with dilution when the purified analyte is unavailable to conduct a true spike-recovery experiment.

VALIDATION METRICS AND ACCEPTANCE CRITERIA

As previously defined, the goal of the validation experiment is to establish that the analytical method is fit for use. Thus for an impurity assay, for example, the goal of the validation experiment should be to show that the sensitivity of the analytical procedure (as measured by the LOD for a limit assay and by the LOQ for a quantitative assay) is adequate to detect a meaningful level of the impurity. Assays for content and potency are usually used to establish that a drug conforms to specifications that have been determined either through clinical trials with the drug or from process/product performance. It is important to point out that the process capability limits should include the manufacturing distribution of the product characteristic under study, the change in that characteristic because of instability under recommended storage conditions, as well as the effects on the measurement of the characteristic because of the performance attributes of the assay. In the end, the analytical method must be capable of reliably discriminating satisfactory from unsatisfactory product against these limits. The portion of the process range that is a result of measurement, including measurement bias as well as measurement variability, serves as the foundation for setting acceptance criteria for assay validation parameters.

Validation parameters related to accuracy are rated on the basis of recovery or bias (bias = 100 – recovery, usually expressed as a percentage), while validation parameters related to random variability are appraised on the basis of variability (usually expressed as % RSD). These can be combined with the process variability to establish the “process capability” of the measured characteristic:^[4]

$$\begin{aligned} \text{CP} &= \frac{\text{Specification range}}{6 \cdot \text{Product range}} \\ &= \frac{\text{Specification range}}{6\sqrt{\sigma_{\text{product}}^2 + \sigma_{\text{assay}}^2 + \text{Bias}^2}} \end{aligned}$$

Process capability, in turn, is related to the percentage of measurements that are likely to fall outside of the specifications. Thus acceptance criteria on the amount of bias and analytical variability can be established based upon the knowledge of the product variability and the desired process capability.

When the limits have not been established for a particular product characteristic, such as during the early development of a drug or biologic, acceptance criteria for an assay attribute might be specified on the basis of a typical

expectation for the analytical method as well as on the nature of the measurement in the particular sample. Thus for example, high-performance liquid chromatography for the active compound in the final formulation of a drug might be typically capable of yielding measurements equal to or less than 10% RSD, while an immunoassay used to measure antigen content in a vaccine might only be capable of achieving up to 20% RSD. Measurement of a residual or an impurity by either method, on the other hand, may only achieve up to 50% RSD, owing to the variable nature of measurement at low analyte concentrations.

VALIDATION DATA ANALYSIS

Analysis of Parameters Related to Accuracy

Analytical accuracy and linearity can be parameterized as a simple linear model, assuming either absolute or relative bias. In one model, if we let μ represent the known analyte content and x is the measured amount, then the accuracy can be expressed as $x = \mu$ at a single concentration, or as $x = \alpha + \beta\mu$, where $\alpha = 0$ and $\beta = 1$, across a series of concentrations. This linear equation can be rewritten as

$$x = \mu + [\alpha + (\beta - 1)\mu].$$

In this parameterization, α is related to the accuracy of the analytical method and represents the constant bias in an assay measurement (usually reported in the units of measurement of the assay), while $(\beta - 1)$ is related to the linearity of the analytical method and represents the proportional bias in an assay measurement (usually reported in the units of measurement in the assay per unit increase in that measurement, e.g., 0.02 μg per microgram increase in content). Data from a spiking experiment can be utilized to estimate α and $\beta - 1$, and these (with statistical confidence limits if the validation experiment has been designed to establish statistical conformance) can be compared with the acceptance criteria established for these parameters.

To illustrate, consider the example in Table 2. A validation study has been performed in which samples have been prepared with five levels of an analyte ([C] in mg), and their

Table 2 Example of Results from a Validation Experiment in Which Five Levels of an Analyte Were Tested in Six Runs of the Assay

[C]	1	2	3	4	5	6	Avg.
3	3.3	3.4	3.2	3.1	3.4	3.3	3.3
4	4.2	4.2	4.2	4.4	4.0	4.3	4.2
5	5.0	4.9	4.9	5.0	4.8	4.9	4.9
6	5.8	5.8	5.6	5.9	5.9	5.7	5.8
7	6.4	6.7	6.7	6.8	6.6	6.4	6.6

content is determined in six runs of an assay. These data are depicted graphically, along with the results from their analysis, in Fig. 1. A linear fit to the data yields the following estimates of intercept (note that the data have been centered in order to obtain a “centered” intercept) and slope:

$$\hat{\alpha}' = -0.04 \text{ } (-0.08, 0.01), \quad \hat{\beta} = 0.81 \text{ } (0.70, 0.85)$$

The slope can be utilized to estimate the bias per unit increase in drug concentration:

$$\hat{\beta} - 1 = -0.19 \text{ } (-0.30, -0.15)$$

This proportional bias is significant, owing to the fact that the confidence interval excludes 0. It is more desirable, however, to react to the magnitude of the bias and to judge that there is an unacceptable nonlinearity when the bias is in excess of a prespecified acceptance limit. Thus there is a 0.2-mg decrease per unit increase in concentration (as much as -0.3 mg per unit decrease in concentration based on the confidence interval). If the range in the concentration of the drug is typically 4–6mg (i.e., a 2-mg range), this would predict that the bias as a result of “nonlinearity” is 0.4 mg (0.6 mg in the confidence interval). This can be judged to be of consequence or not in testing product; for example, if the specification limits on the analyte are 5 ± 1 $\mu\text{g}/\text{dose}$, much of this range will be consumed by the proportional bias, potentially resulting in an undesirable failure rate in the measurement of that analyte.

When the purified analyte is unavailable for spiking, and the levels of the analyte in the validation have been attained through dilution, then the data generated from that series can be alternatively evaluated using the model $x = \alpha\mu^\beta$ (note that μ can represent either the expected concentration upon dilution or the actual dilution). Taking the logs, the data from the dilution series is used to fit the linear model,

$$\log(x) = \log(\alpha) + \beta \log(\mu)$$

Fig. 1 Validation results from an assay demonstrating proportional bias, with low-concentration samples yielding high measurements and high-concentration samples yielding low measurements

The intercept of this model has no practical meaning, while the proportional bias (sometimes called “dilution effect”) can be estimated as $2^{\beta-1} - 1$ if μ is in units of concentration and as $2^{\beta+1} - 1$ if μ is in units of dilution (note that the units of “dilution effect” are percent bias per dilution increment; the dilution increment used here is twofold).

To illustrate, consider the example in Table 3. A dilution series of a sample is performed in each of the five runs of an assay. These data are depicted graphically, along with the results from their analysis, in Fig. 2. A linear fit of log-titer to log-dilution yields an estimated slope equal to $\hat{\beta} = -1.01$ ($-1.04, -0.98$). The corresponding dilution effect is equal to $2^{-1.01+1} - 1 = -0.007$ (i.e., a 0.7% decrease per twofold dilution).

The dilution effect can also be calculated as a function of the estimated slopes for the standard (slope as a function of dilution rather than concentration) and the test sample:

$$\text{Dilution effect} = 2^{1-\hat{\beta}_T/\hat{\beta}_S}$$

with the corresponding standard error a function of the standard error of a ratio:

$$\text{SE}(\hat{\beta}_T/\hat{\beta}_S) = \sqrt{\frac{1}{\hat{\beta}_S^2} \cdot \left[\text{VAR}(\hat{\beta}_T) + (\hat{\beta}_T/\hat{\beta}_S)^2 \cdot \text{VAR}(\hat{\beta}_S) \right]}$$

This has the advantage over the earlier calculation of being a more reliable estimate of the underlying variability in the measurements, coming from the contribution to the estimate of variability from the data for the standard.

Table 3 Example of Results from a Validation Experiment in Which Five Twofold Dilutions of an Analyte were Tested in Five Runs of the Assay

Dilution	1	2	3	4	5	Titer
1	75	90	93	79	72	81
2	43	45	46	35	40	83
4	20	23	22	18	21	83
8	11	10	12	10	10	85
16	4	5	6	4	5	78

Fig. 2 Results from a validation series demonstrating satisfactory linearity, i.e., approximately a twofold decrease in response with twofold dilution

A special case of accuracy comes from a comparison of an experimental analytical method with a validated “referee” method. Paired measurements in the two assays can be made on a panel of samples, and these can be utilized to establish the “linearity” and the accuracy of the experimental method relative to the “referee” method. The paired measurements are a sample from a multivariate population, and the “linearity” of the experimental method to the “referee” method can be estimated using principal component analysis.^[5] A “concordance slope” can be estimated from the elements of the first characteristic vector of the sample covariance matrix (a_{21}, a_{11}):

$$\hat{\beta}_C = \frac{a_{21}}{a_{11}}$$

The standard error of the “concordance slope” is obtained from these along with the other elements of the characteristic value evaluation (a_{i1} is the i th element of the first characteristic vector and l_i is the corresponding characteristic roots):

$$\text{SE}(\hat{\beta}_C) = \sqrt{\left[\frac{V(a_{21})}{a_{21}^2} + \frac{V(a_{11})}{a_{11}^2} - 2 \frac{\text{cov}(a_{21}, a_{11})}{a_{21}a_{11}} \right] \hat{\beta}_C^2}$$

where

$$V(a_{i1}) = \left[\frac{l_i l_j}{n \cdot (l_j - l_i)^2} \right] a_{i2}^2$$

and

$$\text{cov}(a_{21}, a_{11}) = \left[\frac{l_i l_j}{n \cdot (l_j - l_i)^2} \right] a_{12} a_{22}$$

The “concordance slope” can be used, along with the standard error of that estimate, to measure the discordance of the experimental analytical method relative to the “referee” method and its corresponding confidence interval:

$$\text{Discordance} = 2^{\hat{\beta}_C - 1}$$

This is similar to the “dilution effect” discussed earlier and represents the percentage difference in reported potency per twofold increase in result as measured in the “referee” method.

When the two assays are scaled alike, the accuracy of experimental method relative to the “referee” method can be assessed through a simple paired variate analysis. When the percent difference is expected to be constant across the two methods, the data are analyzed on a log scale. An estimate of the simple paired difference in the logs can be used, in conjunction with the standard error of the paired difference, to estimate the percentage difference in

measurements obtained from the experimental procedure relative to the “referee” method.^[6]

$$\bar{d} \pm t_{n-1} s_d / \sqrt{n}$$

$$\text{Percent difference} = 100(e^{\bar{d}} - 1)\%$$

Note that as usual, the significance of the percentage difference should be judged primarily on the basis of practical considerations rather than statistical significance.

The specificity of an analytical procedure can be assessed through an evaluation of the results obtained from a “placebo” sample (i.e., a sample containing all constituents except the analyte of interest) relative to background. A statistical evaluation might be composed of either a comparison of instrument measurements obtained for this “placebo,” with background measurements (i.e., through background-corrected “placebo” measurements), or from measurements made on the “placebo” alone. In either case, an increase over the detection level of the assay would indicate that some constituent of the sample, in addition to analyte, is contributing to the measurement in the sample. This should be assessed by noting that the upper bound on a confidence interval falls below some prespecified level in the assay.

Analysis of Parameters Related to Variability

Estimates of repeatability (intrarun, or within-run, variability) and precision (interrun, or between-run, variability) can be established by performing a variance component analysis on the results obtained from the data generated to assess accuracy and linearity.^[7] Other sources of variability (e.g., laboratories, operators, and reagent lots) can be incorporated into the pattern of runs performed during the validation to estimate the effects of these sources of variability. The expected mean squares are shown in Table 4. From this, $\hat{\sigma}_{\text{withinrun}}^2$ = mean square error (MSE) and $\hat{\sigma}_{\text{betweenrun}}^2$ = (mean square for runs (MSR)–MSE)/5 (note that the MSE is a composite of pure error and the interaction of run and level; pure error could be separated from the interaction by performing replicates at each level; however, the within-run variability will still be reported as the composite of pure error and the level-by-run interaction).

Table 4 Analysis of Variance Table Showing Expected Mean Squares as Functions of Intrarun and Interrun Components of Variability

Effect	df	MS	Estimated mean square	F
Level	4	Mean square for levels (MSL)	$\hat{\sigma}_w^2 + Q(L)$	
Run	5	MSR	$\hat{\sigma}_w^2 + 5\hat{\sigma}_B^2$	MSR/MSE
Error	20	MSE	$\hat{\sigma}_w^2$	

The total variability associated with testing a sample in the assay can be calculated from these variance component estimates as:

$$\hat{\sigma}_{\text{Total}}^2 = \frac{\hat{\sigma}_B^2}{r} + \frac{\hat{\sigma}_w^2}{nr}$$

Note that this is the variance of $\bar{y}$, where r represents the number of independent runs performed on the sample and n represents the number of replicates within a run.

A confidence interval can be established on the total variability as follows:^[8]

$$\begin{aligned} \hat{\sigma}_{\text{Total}}^2 &= \frac{\hat{\sigma}_B^2}{r} + \frac{\hat{\sigma}_w^2}{nr} \\ &= \left(\frac{1}{Jr} \right) \cdot \text{MSR} + \left(\frac{n-J}{Jnr} \right) \cdot \text{MSE} \\ &= c_1 \cdot \text{MSR} + c_2 \cdot \text{MSE} \\ &= \sum_q c_q S_q \end{aligned}$$

where J represents the number of replicates of a sample tested in each run of the assay validation experiment (here $J = 5$ for the number of levels of the sample). The $1 - 2\alpha$ confidence interval on $\hat{\sigma}_{\text{Total}}^2$ becomes:

$$\left[\hat{\sigma}_{\text{Total}}^2 - \sqrt{\sum_q G_q^2 c_q^2 S_q^4}, \hat{\sigma}_{\text{Total}}^2 + \sqrt{\sum_q H_q^2 c_q^2 S_q^4} \right]$$

where

$$G_q = 1 - \frac{1}{F_{\alpha, df_q, \infty}}, H_q = \frac{1}{F_{1-\alpha, df_q, \infty}} - 1, F_{\alpha, df_q, \infty}, F_{1-\alpha, df_q, \infty}$$

represent the percentiles of the F -distribution.

The LOD and the LOQ are calculated using the standard deviation of the responses ($\hat{\sigma}$) and the slope of the calibration curve ($\hat{\beta}$) as $\text{LOD} = 3.3 \hat{\sigma}/\hat{\beta}$ (note, the 3.3 is derived from the 95th percentile of the standard normal distribution, 1.64; here, $2 \times 1.64 = 3.3$, thereby limiting both the false-positive and false-negative error rates to be equal to or less than 5%) and $\text{LOQ} = 10 \hat{\sigma}/\hat{\beta}$ (note, the 10 corresponds to the restriction of no more than 10% RSD in the measurement variability; $\frac{\text{RSD}}{100} = \frac{\hat{\sigma}}{\bar{x}} < 0.10$ gives $\bar{x}$; thus if the restriction was changed to “not more than 20% RSD,” then the LOQ could be calculated as $\text{LOQ} = 5 \hat{\sigma}/\hat{\beta}$).

These estimates do not account for the calibration curve, and they can be improved upon by acknowledging the variability in prediction from the curve.^[9] For a linear fit, the LOD is depicted graphically in Fig. 3. The LOQ can

Fig. 3 Determination of the LOD using the linear fit of the standard curve plus restrictions on the proportions of false positives and false negatives

Fig. 4 Determination of the LOQ using the linear fit of the standard curve and a restriction on the variability (% RSD) in the assay

be calculated as prescribed in the ICH guideline, solving for x_Q in the following equation:

$$LOQ = 10 \left\{ \hat{\sigma} \sqrt{1 + \frac{1}{n} + \frac{(x_Q - \bar{x})^2}{SXX}} \right\}$$

The limit of quantitation is depicted graphically in [Fig. 4](#).

The LOQ is more complicated to calculate from a non-linear calibration function, such as the four-parameter logistic regression equation, and involves the first-order Taylor series expansion of the solution equation for x_Q ^[10] (see the entry on *Assay Development*). The calculation of the LOQ for this equation is illustrated in [Fig. 5](#).

FOLLOW-UP

The information from the analytical method validation can be utilized to establish a testing format for the samples in the assay. In particular, variance component estimates of the within-run and between-run variabilities can be used to predict the total variability associated with a variety of testing formats. For example, consider the case where component estimates have been determined to be equal to

Fig. 5 Quantifiable range determined as limits within which assay variability (% RSD) is less than or equal to 20%

Table 5 Predicted Variability (% RSD) for a Given Number of Runs (r) and a Given Number of Replicates within Each Run (n)

r/n	1	2	3	∞
1	6%	5%	5%	5.0%
2	4%	4%	4%	3.5%
3	3%	3%	3%	2.9%

$\hat{\sigma}_B = 0.05$ (5%) and $\hat{\sigma}_W = 0.03$ (3%). Letting r represent the number of independent runs that will be performed on a sample, and n be the number of replicates within a run, the variabilities are listed in [Table 5](#). Suppose that, because of the process capability, the analytical variability must be restricted to $RSD \leq 3\%$. As can be observed from the table, this cannot be accomplished using a single run of the assay; it must therefore be achieved through a combination of multiple runs with multiple replicates within each run.

ANALYTICAL METHOD QUALITY CONTROL

Assay validation does not end with the formal validation experiment but is continuously assessed through assay quality control. Control measures of variability and bias are utilized to bridge to the assay validation and to warrant the continued reliability of the procedure.

Extra variability in replicates can be detected utilizing standard statistical process control metrics;^[4] detection and prespecified action upon detection can help maintain the variability characteristics of an assay. For example, when the measurement of an analyte is obtained from multiple runs of an assay, those results can be examined by noting the range (either “log(max) – log(min)” or “max – min,” depending upon whether the measurements are scaled proportionally or absolutely). A bound on the range can be derived:

$$\text{Range} \leq \hat{\sigma}_{\text{dimension}} (d_2 + kd_3)$$

where $\hat{\sigma}_{\text{dimension}}$ is the variability in the dimension of replication (here, run to run), d_2 and d_3 are the factors used to scale the standard deviation to a range, and k is a factor representing the desired degree of control (e.g., $k = 2$ represents approximately 95% confidence). Having detected “extra variability,” additional measurements can be obtained, and a result for the sample can be determined from the remainder of the measurements made after the maximum and minimum results have been eliminated from the calculation. When “extra variability” has been identified in instrument replicates of a standard concentration or a dilution of a test sample, that concentration of the standard or dilution of the test sample might be eliminated from subsequent calculations.

Measurements on control sample(s) help identify shifts in scale and therefore bias in a run of an assay. Information in multiple control samples can typically be reduced to one or two meaningful scores, such as an average and/or a slope. These can help isolate problems and provide information regarding the cause of a deviation in a run of an assay. Suppose, for example, that three controls of various levels are used to monitor shifts in sensitivity in the assay. The average can be used to detect absolute shifts, because of some underlying source of constant variability, such as inappropriate preparation of standards or the introduction of significant background. The slope can be used to detect proportional shifts as a result of some underlying source of proportional variability.

Suitability criteria on the performance of column peaks can detect degeneration of a column, while characteristics of the standard curve, such as the slope or EC_{50} (EC_{50} corresponds to C in a four-parameter logistic regression) help predict an assay with atypical or substandard performance.

Care must be taken, however, to avoid either meaningless or redundant controls. The increased false-positive rate inherent in the multiplicity of a control strategy must be considered, and a carefully contrived quality control scheme should acknowledge this.

CONCLUSION

A carefully conceived assay validation should follow assay development, and precede routine implementation of the method for product characterization. The purpose of the validation is to demonstrate that the assay is fundamentally reliable, and possesses operating characteristics that make it *suitable for use*. The statistical estimates collected during the validation can also be used to design a test plan, that provides the maximum reliability for the minimum effort in the laboratory. Most importantly, validation of the assay does not end with the documentation of the validation experiment, but should continue with assay

quality control. The proper choice of control samples and control parameters helps assure the continued validity of the procedure during routine use in the laboratory.

Abstract

In validation of quantitative analytical laboratory procedures, one of the most important characteristics of the accuracy is the linearity. This entry introduces experimental design and statistical testing procedures for testing linearity based on specific criteria.

Keywords: Allowable limit; General pivotal quantities; Linearity; Quantitative analytical laboratory methods.

INTRODUCTION

In validation of quantitative analytical laboratory procedures, one of the most important characteristics of the accuracy is the linearity. The ICH Q2A guideline^[1] defines the linearity of an analytical method as its ability (within a given range) to obtain the test results, which are directly proportional to the concentration (amount) of the analyte in the test sample. The objective for evaluation of linearity is to validate existence of a mathematically verified straight-line relationship between the observed values and the true concentrations or activities of the analyte. Linearity represents the simplest mathematical relationship and it also permits simple and easy interpolations of results for clinical practitioners. The approved Clinical Laboratory Standard Institute (CLSI) guideline EP6-A^[2] recommends that at least five solutions of different concentration levels across the anticipated range be included in an experiment for evaluation of linearity. At each concentration level, two to four replicates should be run. According to the evaluation criterion suggested by EP6-A,^[2] if the difference between the best-fit non-linear polynomial curve and simple linear regression equation at each concentration is smaller than some pre-defined allowable bias δ_0 , the linearity then can be claimed. For instance, in Fig. 1, it shows that the linearity is claimed because the magnitude of deviation from linear regression at all concentrations for the best-fit model are less than δ_0 , while the linearity cannot be claimed in Fig. 2 since the magnitude of deviation from linear regression at concentration S2, S3 and S4 for the best-fit model are greater than δ_0 .

The evaluation criterion of EP6-A is a disaggregate criterion since it requires the difference between the best-fit non-linear polynomial curve and simple linear regression equation must be smaller than pre-defined allowable limit at each concentration. On the other hand, Hsieh et al.^[3] propose the sum of squares of deviation from linearity (SSDL) as an unscaled aggregate criterion for assessment of linearity. The linearity of an assay method can be claimed at α significance level if observed SSDL is smaller than the upper $100(1 - \alpha)\%$ generalized confidence limit of SSDL. In addition, two scaled aggregate criteria including the linearity average deviation from linearity (ADL) and the coefficient of variation of the deviation from linearity (CVDL) are also proposed by Kroll et al.^[4] and Liu et al.,^[6] respectively. The ADL is scaled by the mean concentration while CVDL is scaled by the square of the variability of the best-fit model. The disaggregate criterion is in general more conservative than the aggregate criterion. On the other hand, compared with the unscaled aggregate criterion, the scaled aggregate criterion, which is the measures expressed in the relative magnitude of bias based on the unitless scaled deviations from linearity, may provide a better and more meaningful interpretation for the accuracy of analytical procedures.

In this entry, we will introduce the experimental design suggested by EP6-A guideline^[2] for assessment of linearity firstly. The evaluation criteria with the corresponding statistical hypotheses will then be provided. In the latter part of the entry, we will review several statistical testing procedures for assessing of linearity based on the evaluation

Fig. 1 Acceptance of linearity by CLSI EP6-A guideline

Fig. 2 Failure of linearity by CLSI EP6-A guideline

criteria introduced above. The simulation results for comparing the empirical size and powers of each method will be discussed. Two numerical examples will be used to discuss the applications of the introduced methods. Concluding remarks will be given at the end.

EXPERIMENT DESIGN

The approved CLSI guideline EP6-A^[2] recommends that the experiment for linearity assessment should be conducted at least five solutions of different concentrations run at least in duplicates. Let Y_{ij} be the test result of replicate j at concentration X_i , where $j = 1, \dots, j$; $i = 1, \dots, L$. The approved CLSI guideline EP6-A considers the following linear, quadratic, and cubic models fitting the data obtained from the experiment:

Linear (First order):

$$\mu_{Li} = \alpha' + \beta_1' X_i$$

Quadratic (Second-order polynomial):

$$\mu_{Qi} = \alpha'' + \beta_1'' X_i + \beta_2'' X_i^2 \quad (1)$$

or

Cubic (Third-order polynomial):

$$\mu_{Ci} = \alpha''' + \beta_1''' X_i + \beta_2''' X_i^2 + \beta_3''' X_i^3$$

where μ_{Li} , μ_{Qi} , and μ_{Ci} are the predicted mean of the corresponding models and α' , α'' , α''' ; β_1' , β_1'' , β_1''' ; β_2'' , β_2''' , and β_3''' , are the intercepts, regression coefficients for the corresponding models in Eq. 1. The best-fit model is the model such that lack-of-fit is not statistically significant and the repeatability meets the manufacturer's claim. In addition, for the purpose of illustration, the random error is assumed to be approximately constant rather proportional in the range of concentrations considered in the experiment.

The spirit of the EP6-A guideline^[2] is to determine the concentrations(s) where an assay method is not linear and the extent of the non-linearity at that level. As addressed in the guideline "The guideline emphasizes the necessity that each user establishes his or her requirements for linearity, or the allowable error due to nonlinearity. It also places less importance on global tests such as Lack-of-Fit test for linearity across the tested range. Global tests merely indicate that statistically significant non-linearity exists; they do not show where that non-linearity is, nor do they show the magnitude of the error." Therefore, even if the best-fit model is a non-linear model, it does not necessarily imply that the assay cannot be concluded linear. Based on the above concept, the guideline proposes the following rule in instead of Global test for assessing linearity: if the best-fit model is the linear model over the some range of concentrations employed in the experiment, then the assay method can be concluded to be linear over the some range of concentrations. However, if the best-fit model is not linear, the linearity of the analytical procedure can still be claimed if the magnitude of deviations from the linearity at each concentration is within some pre-specified allowable limit of δ_0 as showed in Fig. 1.

EVALUATION CRITERIA

EP6-A's Criterion

The EP6-A defines the best-fit model is the one such that the lack-of-fit of the model is not statistically significant and repeatability meets the manufacturer's claim. The deviation from linearity at concentration i is defined as the difference between the predicted mean of the best-fit model and that of the linear model at concentration i .

The linearity of an analytical procedure can be claimed if the one of following is conditions are satisfied:

- If the best-fit model is the linear model over the same range of concentrations employed in the experiment.
- If the best-fit model is not linear, the magnitude of deviations from the linearity at each concentration is within some pre-specified allowable limit.

Let μ_{pi} denote the predicted mean of the best-fit model, where μ_{pi} can be either μ_{Qi} or μ_{Ci} . The deviation from linearity at each concentration level is defined as the difference in the predicted means between the best-fit nonlinear model and linear model $\mu_{pi} - \mu_{Li}$. Let δ_0 be some pre-specified allowable margin. The linearity of an assay can be concluded by EP6-A's criterion if

$$|\mu_{pi} - \mu_{Li}| < \delta_0, \quad i = 1, \dots, L. \quad (2)$$

The corresponding statistical hypothesis can be expressed as

$$H_{0i} : |\mu_{pi} - \mu_{Li}| \geq \delta_0 \text{ vs. } H_{ai} : |\mu_{pi} - \mu_{Li}| < \delta_0, \quad \text{for all } i = 1, \dots, L. \quad (3)$$

Since the hypothesis in Eq. (3) requires all differences in the predicted means between the best-fitting and linear models be within the pre-specified allowable limit, it is a disaggregate criterion.

Sum of Squares of Deviation from Linearity (SSDL)

Considering the evaluation proposed by EP6-A guideline^[2] in Eq. 2, a natural summary measure for evaluation of linearity is the sum of squares of deviation (SSDL) from linearity:^[3]

$$\tau = \text{SSDL} = \sum_{i=1}^L (\mu_{pi} - \mu_{Li})^2. \quad (4)$$

It follows that the hypotheses for proving the assay linearity can be formulated based on SSDL as follows:

$$H_0 : \sum_{i=1}^L (\mu_{pi} - \mu_{Li})^2 \geq L\delta_0^2 \text{ vs. } H_a : \sum_{i=1}^L (\mu_{pi} - \mu_{Li})^2 < L\delta_0^2 \quad (5)$$

or equivalently

$$H_0 : \sum_{i=1}^L (\mu_{pi} - \mu_{Li})^2 / L \geq \delta_0^2 \text{ vs. } H_a : \sum_{i=1}^L (\mu_{pi} - \mu_{Li})^2 / L < \delta_0^2$$

The SSDL is an aggregate criterion since it is the sum of squares of the differences in the predicted means between the best-fit and linear models

Average Deviation from Linearity (ADL)

The SSDL is the sum of squares of unscaled deviations from linearity and its unit is the square of the unit of concentration of analyte. Sometimes, the measures expressed in the relative magnitude of bias based on the unitless scaled deviations from linearity may provide a better and more meaningful interpretation for the accuracy of analytical procedures. The first type of the scaled deviations is the deviations scaled by μ , the mean concentration for all solutions of the assay:

$$(\mu_{pi} - \mu_{Li}) / \mu$$

Kroll et al.^[4] considers the average deviation from linearity (ADL) for assessment of linearity. The ADL is defined as

$$\theta = \text{ADL} = \frac{\sqrt{\sum_{i=1}^L (\mu_{pi} - \mu_{Li})^2 / L}}{\mu}, \quad (6)$$

where μ is the population mean concentration for all solutions of the assay.

The ADL is a scaled deviation defined as the square root of sum of squares of the difference in predicted means between the best-fit and linear models. The hypothesis for evaluation of linearity based on ADL proposed by Hsieh and Liu^[5] is given as

$$H_0 : \theta \leq \theta_0 \text{ vs. } H_a : \theta > \theta_0, \quad (7)$$

where θ_0 is the maximum allowable average deviation from linearity. Because ADL is a function of standardized sum of squares of the differences in the predicted means between the best-fit and linear models, it is also an aggregate criterion.

Coefficient of Variation of the Deviations from Linearity (CVDL)

The second type of the scaled deviations is the deviations scaled by σ , the variability or repeatability of the best-fit model:

$$(\mu_{pi} - \mu_{Li}) / \sigma$$

The CVDL^[6] for assessment of linearity is the square root of the average sum of squares of the scaled deviations by σ :

$$\eta = \text{CVDL} = \frac{\sqrt{\sum_{i=1}^L (\mu_{pi} - \mu_{Li})^2 / L}}{\sigma}.$$

The hypotheses for evaluation of linearity is given for CVDL as

$$H_0: \eta \geq \eta_0 \text{ vs. } H_a: \eta < \eta_0. \quad (8)$$

where η_0 is the allowable limit of CVDL. The CVDL is also an aggregate criterion. Furthermore, the relationship among τ , θ , and η can be given as

$$\tau = L(\theta\mu)^2 = L(\eta\sigma)^2 \quad (9)$$

STATISTICAL TESTING PROCEDURES

Two One-sided Tests (TOST) Procedures

Let $\hat{Y}_{Pi}$ and $\hat{Y}_{Li}$ denote the least squared (LS) estimators of the predicted mean of the best-fit and linear models, respectively, where

$$\hat{Y}_{Li} = a' + b'_2 X_i, \text{ and}$$

$$\hat{Y}_{Pi} = \begin{cases} a'' + b''_1 X_i + b''_2 X_i^2, & \text{if the best-fit model is quadratic,} \\ a''' + b'''_1 X_i + b'''_2 X_i^2 + b'''_3 X_i^3, & \text{if the best-fit model is cubic,} \end{cases}$$

and a' , a'' , a''' ; b'_1 , b'_2 , b'_3 ; b''_1 , b''_2 , b''_3 ; b'''_1 , b'''_2 , b'''_3 are the LS estimators of the intercepts, regression coefficients for the corresponding models in Eq. (1).

The estimation method suggested by the EP6-A guideline^[2] conclude the linearity of the proposed analytical method concluded if

$$|\hat{Y}_{Pi} - \hat{Y}_{Li}| < \delta_0, \quad \text{for } i = 1, \dots, L.$$

However, the estimation method may inflate the type I error rate in assessment of linearity because it completely ignores the variability and distribution associated with the estimators. The linearity of an assay is claimed at the α significance level if the $(1-2\alpha)100\%$ confidence interval for $\alpha_p - \alpha_L$ given by

$$(\hat{Y}_{Pi} - \hat{Y}_{Li}) \pm t_{\alpha, LJ-d-1} \hat{\sigma}_{di}, \quad (10)$$

is within $(-\delta_0, \delta_0)$, for $i=1, \dots, I''$.

Estimators of SSDL, ADL, and CVDL

Define

$\mathbf{Y}$ = the $LJ \times 1$ vector of observations,

$\mathbf{X}_L = (\mathbf{1}, \mathbf{X})$.

$\mathbf{X}_P = \begin{cases} (\mathbf{1}, \mathbf{X}, \mathbf{X}_2), & \text{if the best-fit model is quadratic,} \\ (\mathbf{1}, \mathbf{X}, \mathbf{X}_2, \mathbf{X}_3), & \text{if the best-fit model is cubic, and} \end{cases}$

$\Delta = \mu_P - \mu_L$,

where $\mu_P = LJ \times 1$ predicted mean vector of best-fit polynomial model, μ_L = the $LJ \times 1$ predicted mean vector of linear model, and $\mathbf{1}$ is $LJ \times 1$ vector of 1s $\mathbf{X} = (\mathbf{X}_i)$, $\mathbf{X}_2 = (\mathbf{X}_i^2)$, and $\mathbf{X}_3 = (\mathbf{X}_i^3)$.

Then a least squares unbiased estimator for the vector of the deviations from linearity Δ , is given as

$$\hat{\Delta} = \mathbf{H}\mathbf{Y},$$

where $\mathbf{H} = (\mathbf{H}_P - \mathbf{H}_L)$, $\mathbf{H}_P$ and $\mathbf{H}_L$ be the projection matrices corresponding to the column spaces spanned by the design matrices of the best-fit and linear models, respectively, that is, $\mathbf{H}_P = \mathbf{X}_P(\mathbf{X}'_P \mathbf{X}_P)^{-1} \mathbf{X}'_P$ and $\mathbf{H}_L = \mathbf{X}_L(\mathbf{X}'_L \mathbf{X}_L)^{-1} \mathbf{X}'_L$.

It follows that $\hat{\Delta}$ is distributed as a multivariate normal distribution with mean vector Δ and covariance matrix $\mathbf{H}\mathbf{H}'\sigma^2$.

An estimator of SSD, ADL, and CVDL can be expressed by the least squares unbiased estimator for Δ as follows:

$$\hat{\tau} = (\hat{\Delta}'\hat{\Delta})/J.$$

$$\hat{\theta} = \frac{\sqrt{\sum_{i=1}^L (\hat{Y}_{Pi} - \hat{Y}_{Li})^2 / L}}{\bar{Y}} = \frac{\sqrt{\hat{\tau}/L}}{(\bar{Y})/LJ}, \quad (11)$$

$$\hat{\eta} = \frac{\sqrt{\sum_{i=1}^L (\hat{Y}_{Pi} - \hat{Y}_{Li})^2 / L}}{s} = \sqrt{\frac{\hat{\tau}/L}{[\mathbf{Y}'(\mathbf{I} - \mathbf{H}_P)\mathbf{Y}]/(LJ - d - 1)}},$$

Where $\hat{Y}$ is the observed mean concentration for all solutions of the assay, s is the square root of the residual mean square obtained from the best-fit model with degrees of freedom of $LJ-d-1$, and d is the degrees of freedom for regression of the best-fit model, respectively.

Generalized Pivotal Quantity Approach

Generalized Pivotal Quantity for SSDL, ADL, and CVDL

Suppose that U is a random variable whose distribution depends on a vector of unknown parameters $\xi = (\theta, \lambda)$, where θ is a parameter of interest and λ is a vector of nuisance parameter. Let $\mathbf{U}$ be a random sample from U and $\mathbf{u}$ be the observed value of $\mathbf{U}$. Also let $\mathbf{R} = \mathbf{R}(\mathbf{U}; \mathbf{u}, \xi)$ be a function of $\mathbf{U}$, $\mathbf{u}$, and ξ . The random quantity $\mathbf{R}$ is said to be a GPQ if satisfies the following two conditions:

- $\mathbf{R}$ has a probability distribution that is free of unknown parameter.
- The observed pivotal of R , say $r = \mathbf{R}(\mathbf{U}; \mathbf{u}, \xi)$, does not depend upon nuisance parameters λ . In other words, r is only a function of $\mathbf{u}$ and θ .

In particular, the GPQ is called the fiducial generalized pivotal quantity (FGPQ) when the observed quantity $r = \theta$. It has been shown that the generalized confidence interval (GCI) based on FGPQ are proven to have asymptotically correct frequent coverage probability.^[7] Therefore, an upper $100(1 - \alpha)$ th percentile GCI for θ is given by $R_{1-\alpha}$, where $R_{1-\alpha}$ are the $100(1 - \alpha)$ th percentile of the distribution of $\mathbf{R}$. The percentiles of $\mathbf{R}$ can be estimated using Monte Carlo algorithms.

A GPQ for SSDL^[3] is given as

$$R_\tau = \frac{1}{J} (\mathbf{R}_\Delta)' (\mathbf{R}_\Delta), \quad (12)$$

where $\mathbf{R}_\Delta = \mathbf{H}\mathbf{y} - [\mathbf{R}_{\sigma^2} \mathbf{H}\mathbf{H}']^{1/2} \mathbf{Z}$, a pivotal quantity for Δ , $R_{\sigma^2} = \frac{(\mathbf{L}\mathbf{J} - d - 1)S^2}{V}$, a pivotal quantity for σ^2 ,

$$\mathbf{Z} = \sum^{-1/2} [\hat{\Delta} - \Delta], V = \frac{(\mathbf{L}\mathbf{J} - d - L)S^2}{\sigma^2}, \sum = \sigma^2 \mathbf{H}\mathbf{H}',$$

where matrix $\Lambda^{1/2}$ denotes the positive definite square root of a positive definite matrix Λ and $\Lambda^{-1/2} = (\Lambda^{1/2})^{-1}$.

In addition, $\hat{\Lambda}$ can be expressed by the projection matrices as

$$\begin{aligned} \hat{\Lambda} &= \mathbf{H}\mathbf{Y} \\ &= (\mathbf{H}_p - \mathbf{H}_L)\mathbf{Y} \\ &= [(\mathbf{I} - \mathbf{H}_L) - (\mathbf{I} - \mathbf{H}_p)]\mathbf{Y}. \end{aligned}$$

Because $\bar{\mathbf{Y}} = (\mathbf{I}'\mathbf{Y})/LJ$ and $\mathbf{I}'[(\mathbf{I} - \mathbf{H}_L) - (\mathbf{I} - \mathbf{H}_p)] = 0$, $\bar{\mathbf{Y}}$ and $\hat{\Delta}$ are also independent. It is straightforward to verify that the estimators $\hat{\Delta}$, S^2 and $\mathbf{Y}$ are associated with pivotal quantities $\mathbf{Z}$, V , and Z_μ , which are independent with the following distributions:

$$\begin{aligned} \mathbf{Z} &= \sum^{-1/2} [\hat{\Delta} - \Delta] \sim \mathbf{N}_{LJ}(\mathbf{0}, \mathbf{I}), \\ V &= \frac{(\mathbf{L}\mathbf{J} - d - 1)S^2}{\sigma^2} \sim \chi_{LJ-d-1}^2, \end{aligned}$$

and

$$Z_\mu = \frac{\bar{\mathbf{Y}} - \mu}{\sqrt{\sigma^2/LJ}} \sim N(0, 1), \quad (13)$$

where $\mathbf{N}_{LJ}(\mathbf{0}, \mathbf{I})$, χ_{LJ-d-1}^2 and $N(0, 1)$ denote the multivariate standard normal distribution with $LJ \times 1$ random vector, the chi-square random variable with $LJ - d - 1$ degrees and the univariate standard normal distribution, respectively.

It follows that a GPQ for μ is given as

$$\begin{aligned} R_\mu &= \bar{\mathbf{y}} - \frac{1}{\sqrt{LJ}} \sqrt{R_{\sigma^2} Z_\mu} \\ &= \bar{\mathbf{y}} - \frac{1}{\sqrt{LJ}} \sqrt{\frac{S^2 \sigma^2}{S^2}} \frac{(\bar{\mathbf{Y}} - \mu)}{\sqrt{\sigma^2/LJ}}, \end{aligned} \quad (14)$$

where R_{σ^2} is the generalized pivotal quantity for σ^2 defined in Eq. (12).

From Eqs. (12–14), the distributions of $\mathbf{R}_\Delta$, R_{σ^2} , and R_μ are free of their respective nuisance parameters. In addition, it is readily to verify when $\hat{\Delta}$, S^2 and $\bar{\mathbf{Y}}$ are substituted by their observed values, then $(\mathbf{R}_\Delta, R_{\sigma^2}, \text{ and } R_\mu) = (\Delta, \sigma^2, \mu)$. Hence, they fulfill the requirement (a) and (b) of GPQ's given above.

As a result, generalized pivotal quantities for ADL and CVDL^[6] can be obtained respectively as

$$R_\theta = \frac{\sqrt{R_\tau/L}}{R_\mu}, \quad (15)$$

and

$$R_\eta = \frac{\sqrt{R_\tau/L}}{R_{\sigma^2}}, \quad (16)$$

where R_τ , R_μ , and R_{σ^2} are defined in Eqs. 12 and 14.

Generalized Pivotal Quantity for SSDL, ADL, and CVDL

An upper $100(1 - \alpha)$ th percentile GCI for SSDL, ADL, and CVDL can be obtained from the following Monte-Carlo algorithm:

- Step 1:** Choose a large simulation sample size, say $K = 10,000$. For k equal to 1 through K , carry out the following two steps.
- Step 2:** Independently generate $LJ \times 1$ standard normal random vector $\mathbf{Z}$, univariate standard normal variable Z_μ , and central chi-square random variables V with degree of freedom $LJ - d - 1$.
- Step 3:** For the realized values of $\mathbf{Y}$ and S^2 , compute R_τ , R_θ , and R_η as defined in Eqs. (12), (15), and (16), respectively.

The required upper $100(1 - \alpha)$ th percentiles of the distribution of GPQ for SSDL (or ADL or CVDL), which is also the upper $100(1 - \alpha)$ th generalized confidence limit for $\theta(\eta)$, is then estimated by the $100(1 - \alpha)$ th sample percentiles of the collection of $K = 10,000$ realizations $R_{\tau,1}$ (or $R_{\theta,1}$ or $R_{\eta,1}$), $R_{\tau,2}$ (or $R_{\theta,2}$ or $R_{\eta,2}$),, $R_{\tau,10000}$ (or $R_{\theta,10000}$ or $R_{\eta,10000}$).

Statistical Testing Procedure

The upper $100(1 - \alpha)\%$ generalized confidence limits for SSDL or ADL or CVDL based on GPQ can be used to test their respective statistical hypotheses in Eqs. (5) or (7) or (8) for linearity. The linearity of an analytical method is concluded at the α significance level if the upper $100(1 - \alpha)\%$ generalized confidence limit for SSDL or ADL or CVDL is less than $L\delta_0$ or θ_0 or η_0 .

SIMULATION STUDY

The simulation studies are performed to compare the empirical sizes between disaggregate-criterion based estimation method and TOST procedures, and which among three aggregate-criterion based GPQ-SSDL, GPQ-ADL, and GPQ-CVDL methods under the various combination of parameters of number of replicates, number of concentration level and standard deviation of normal random error of the best-fit model. For each of combinations, 5,000 random samples are generated for comparisons of estimation and TOST methods, whereas 10,000 random samples are generated for comparison of three GPQ methods. Therefore, for the 5% nominal significance level, a simulation study with 5,000 random samples implies that 95% of the empirical sizes evaluated at the equivalence limits will be within 0.04396 and 0.05604 if the proposed methods can adequately control the size at the nominal level of 0.05. On the other hand, the size at the nominal level of 0.05 can be adequately controlled if the empirical sizes are within 0.0457 and 0.0543 for ten thousand (10,000) random samples. As presented in Table 1, only 8.33% of the empirical sizes (1/12) of TOST method are not included in (0.04395, 0.05604), while all of the empirical sizes of the estimation method are between 0.4930 and 0.5066. Recall that the estimation method suggested in the approved CLSI guideline EP6-A^[2] ignores the variation of the estimates of $\mu_{pi} - \mu_{ci}$. Under the normal assumption, the size should be equal to 0.5 as confirmed by the empirical sizes of the simulation. With respect to the comparison of GPQ-SSDL, GPQ-ADL, and GPQ-CVDL methods, all of empirical sizes of the GPQ methods based on SSDL, ADL, and CVDL presented in Table 2 are within the range between 0.0457 and 0.0543. The simulation results reveal that the

GPQ-based methods for SSDL, ADL, and CVDL can adequately control the size at the nominal level. Fig. 3 presents the empirical powers of the three aggregate-criterion based method. The figure demonstrates that the GPQ-ADL procedure is uniformly more powerful than the GPQ-SSDL and GPQ-CVDL methods.

NUMERICAL EXAMPLES

Estimation Method Vs. TOST Method

We consider an experiment for evaluation of the linearity of a new analytical procedure for determination of β -HCG (β -Human Chorionic Gonadotropic, mIU/mL). The design consists of five dilutions with two replicates at each dilution of concentrations. Table 3 presents a set of hypothetical measurements under the design described above. For the purpose of the illustration, the allowable limit of $|\mu_{pi} - \mu_{Li}|$ is set as 0.4 for the estimation method suggested in the approved CLSI guideline EP6-A, and for the TOST procedure. The cubic model is the best-fit model recommended by the approved CLSI guideline EP6-A for the data in Table 3.

Table 4 presents the results of linearity of the two methods. With respect to the estimation method, the observed differences in the predicted means between the cubic and linear regression models at all dilutions are within the allowable margin of ± 0.4 . As a result, the linearity is claimed by the estimation method. On the other hand, the results of the TOST procedure show that the 95% confidence intervals for $\mu_{pi} - \mu_{ci}$ at the first two dilutions are not contained within $(-0.4, 0.4)$. With respect to hypotheses in Eq. 10, the analytical method cannot be concluded linear at the 5% significance level. Because the estimation

4	4.36	4.39
5	5.10	5.00

method completely ignores the variability in the observed differences in the predicted means, its conclusion is made without any statement of the probability of type I error. However, in fact, as demonstrated by the simulation, the probability of type I error of the estimation method far exceeds its nominal significance level.

GPQ-SSDL Method versus GPQ-ADL Method versus GPQ-CVDL Method

The first five concentrations given in Example 2 of CLSI guideline EP6-A^[2] illustrate the proposed testing procedures in evaluation of linearity of an analytical procedure.

Following EP6-A,^[2] the criterion of $|\mu_{p_i} - \mu_{L_i}|$ for linearity is set as 0.2 mg/dL for all five concentrations. In this example, the allowable margin of percent bound for ADL is set as 0.05 for all methods based on ADL as suggested by Kroll et al.^[4] On the other hand, the allowable limit of the GPQ-based SSDL is set as 0.2 which is calculated by square of 0.2 mg/dL multiplying five concentrations. We also assume that the allowable repeatability set by the manufacturer is 0.2. Therefore, the allowable margin of the GPQ-based CVDL is 1, which is equal to the square root of the value computed by $\tau = L(\eta\sigma)^2$. The quadratic model is the best-fit model among the three models recommended by the approved CLSI guideline EP6-A^[2] for the data in Table 5.

The results of the three GPQ-based procedures are provided in Table 6. The 95% upper confidence limit for the ADL computed by the GPQ method is 0.0218 which is smaller than the allowable upper limit of 0.05. Hence, the linearity of the analytical procedure can be concluded at the 5% significance level by the GPQ-based ADL procedure. On the other hand, the 95% upper confidence limits for SSDL of the GPQ-based SSDL and CVDL methods are 0.2471 and 1.9125, respectively. Both 95% upper

Table 6 Results of the Linearity Evaluation by Three Different Methods

Method	Sample statistic/critical value or allowable bound		Conclusion
GPQ-based SSDL	Upper 95% C.L.	0.2471	Nonlinear
	Allowable upper bound	0.2	
GPQ-based CVDL	Upper 95% C.L.	1.9125	Nonlinear
	Allowable upper bound	1	
GPQ-based ADL	Upper 95% C.L.	0.0218	Linear
	Allowable upper bound	0.05	

95% C.L.: Upper 95% Confidence limit.

confidence limits are larger than their respective allowable upper limits of 0.2 and 1. As a result, both methods can not conclude the linearity of the analytical procedure at the 5% significance level. The results presented above show the different conclusions between the GPQ-based methods. As shown in simulation results, all three GPQ-based methods can control the size at the nominal size of 0.05, the GPQ-based ADL method is uniformly more powerful than the other two GPQ-based methods. This might be one the reasons why the linearity can be claimed by the GPQ-based ADL method.

CONCLUDING REMARKS

One of the most important characteristics for evaluation of accuracy and precision in assay validation is linearity. Even though the best-fit model is not linear, linearity of the analytical procedure can still be claimed if the difference in the predicted means between the best-fit and linear models is smaller than some pre-specified allowable limit at all concentrations employed in the validation experiment. As a result, the deviation from linearity is the fundamental unit for assessment of bias for evaluation of linearity.

In this entry, we introduced the TOST procedure for the disaggregate criterion as well as the GPQ-based

procedures for the difference aggregate criteria. All of the proposed procedures show the good performance in controlling the size and provide sufficient power for assessment of linearity in assay validation. In addition, the evaluation procedure based on the disaggregate criterion is more conservative than which based on the aggregate criterion because it requires that the difference in predicted mean between the best-fit model and linear models for all solutions be within the pre-specified limit, while the aggregate criterion only requires the magnitude of sum of deviations from linearity be controlled within a aggregate limit. The choice of the disaggregate-criterion based procedure and aggregate-criterion based procedure may depend on how accuracy the assay method is required. In addition, although the GPQ-based ADL procedure is recommended to be used for assessment of linearity in assay validation because it is the uniformly more powerful than the other two GPQ-based methods. However, one may consider using CVDL as the criterion for assay validation if he or she would like to evaluate accuracy and reliability simultaneously.

ACKNOWLEDGMENT

The authors would like to thank the editor of EBS, Dr. Shein-Chung Chow, for inviting us to contribute this entry.

Abstract

In this entry, we discuss two variants of a Bayesian two-stage design for clinical trials. Through a specific example, the entry also discusses how these designs can be used in practice.

Keywords: Bayesian; Dual threshold design; Oncology; Phase II clinical trial; Sample size; Single threshold design.

INTRODUCTION

Many different designs have been proposed and used for phase II oncology clinical trials. The majority of these are based on frequentist statistical approaches. Bayesian methods provide an alternative to frequentist approaches, allowing for the incorporation of relevant prior information and the presentation of the trial results in a manner which some feel is more intuitive and helpful. In this article, we discuss two variants of a Bayesian two-stage design for such clinical trials.^[1] The designs determine the overall sample size on the basis of achieving a minimum posterior probability of exceeding the pre-specified target response rate should the trial data really suggest a positive outcome.

We give sample size tables and cutoff response rates for decisions for these two-stage designs. We also discuss how the designs can be used in practice, using an example of an actual phase II trial involving the treatment of metastatic nasopharyngeal cancer.^[2] We also discuss adaptations to these designs that have been proposed by Mayo and Gajewski^[3,4] and Sambucini.^[5]

PHASE II CLINICAL TRIAL DESIGNS

The process of testing a new therapy for the treatment of a disease involves many stages. In oncology, the typical

process involves a new drug first undergoing extensive development and testing in the laboratory. Once this is done, and the drug is felt to be ready for testing in human subjects, a phase I trial is conducted. The purpose of a phase I trial is to study the drug's toxicity in humans and to identify the "best" dose to be used (in diseases like cancer, this is typically the highest dose which does not result in excessive toxicity). Following this, a phase II trial using this "best" dose is then conducted. The goal of such a trial is to assess the effect of the drug on the disease in question to determine if it should be further tested in a large-scale randomized phase III trial, to determine its efficacy. If such a decision is made, a phase III trial is then conducted to directly compare the new drug with other compounds being used to treat the condition. Phase II clinical trials thus play an important role in the development and testing of a new therapy. Here, by "new," we refer not just to totally new compounds but also to established compounds that are to be tested within a new multi-drug combination therapy for the disease in question.

Phase II clinical trial designs can be single-stage or multi-stage, single-arm or randomized multi-arm. Single-stage designs include the Fleming^[6] and A'Hern^[7] designs. As for two-stage single-arm designs, those that are commonly used include that of Gehan^[8] and the Simon optimal and minimax designs.^[9] Other designs include those by Sposto and Gaynon,^[10] which take into account patient heterogeneity in the design, and an adaptive two-stage design by Lin and Shih,^[11] which allows investigators who are uncertain about the target outcome proportion to specify two-target outcome proportions. The decision whether to proceed

Notes: Some of this article has been adapted from: Tan, S.B.; Machin, D. Bayesian two-stage designs for phase II clinical trials. *Stat. Med.* 2002, 21 (14), 1991–2012.

to Stage 2 of the trial and the sample size for stage two will depend on the effect size experienced at stage one. Trial designs for randomized multi-arm designs have also been developed and utilized, including the randomized selection design proposed by Simon et al.^[12] for binary endpoints and by Liu et al.^[13] for time-to-event endpoints.

There has also been increasing interest in the use of time-to-event endpoints, such as progression-free survival, in the design of phase II oncology clinical trials. In part, this is driven by the large number of regimens that have shown promising activity in single-arm phase II trials (that used tumor response as the primary endpoint of interest) but fail to demonstrate superiority in subsequent phase III trials. This has raised interest and discussion in the use of randomized phase II trial designs with the standard treatment as the control arm.^[14–17] Despite that, there remains a clear role for single-arm phase II designs with tumor response rates as the primary outcome of interest. In particular, as highlighted by Cannistra,^[16] they remain appropriate in situations where the behavior of historical controls has remained stable over time, or the likelihood of response to standard treatment options is low, or the desired treatment effect size is large, or the drug's mechanism of action is expected to be cytotoxic as opposed to cytostatic (permitting the use of response as an endpoint).

It should be noted that all these designs, and many others like them, are based on frequentist statistical approaches. These usually require the specification of various inputs, including a fixed target response rate for the new treatment as well as limits on the type I and type II errors.

The main goal of a phase II trial is not to obtain a precise estimate of the effect (response rate) of the new drug, but rather to accept or reject the drug for further testing in a phase III trial. Nevertheless, the analysis of the trial results typically includes the obtaining of an estimate of the true response proportion, along with the associated 95% confidence interval (CI). Such an analysis does not always answer the question of principal interest to the investigator. For example, even if the point estimate of the response rate exceeds the pre-specified target value, much lower rates may nevertheless be consistent with the CI reported. Thus the investigator might rather wish to know the probability that the true response proportion exceeds the pre-specified target value. Only if this probability is “high” is a subsequent phase III trial justified. With a Bayesian approach, we can obtain the posterior probability distribution of the true response proportion. From this we can then compute the probability that the true response proportion falls within any pre-specified region of interest, including the region above the target value. A Bayesian design also allows for the formal incorporation of relevant information from other sources of evidence in the monitoring and analysis of the phase II trial.

Several Bayesian designs have been proposed for phase II clinical trials, see for example, the methods proposed by Thall,^[18–23] Heitjan,^[24] Sylvester,^[25–27] Mayo and Gajewski,^[3,4] Sambucini,^[5] and Huang et al.^[28] Review

articles on the use of Bayesian statistical methods for clinical trials in general have been written by Berry^[29] and Zohar et al.^[30] In particular, Berry^[29] describes their use in the design and analysis of trials and emphasizes their value for the whole drug development process. Zohar et al.^[30] focuses on design and conduct issues specific to phase II single-arm trials with binary outcomes.

To be specific, Thall and Simon propose a design that, in its simplest form,^[18] involves the continual accrual of patients until the new drug is shown with high posterior probability to be either promising or not promising or until a pre-determined maximum sample size is reached. Their design requires the specification of an informative clinical prior^[31] for the response rate of the “standard” drug and a non-informative clinical prior for the response rate of the new drug. Here and throughout, by “standard” we mean the drug that has been found to be the best to date. Thall and Wathen propose a similar design that also takes account of between patient heterogeneity.^[23]

In contrast, Heitjan's design^[24] does not require the elicitation of the investigators' clinical prior beliefs for the new drug. Instead it requires the specification of hypothetical skeptical and enthusiastic priors.^[31] These represent the prior beliefs of a skeptic (or an enthusiast as appropriate) with regards to the response rate of the drug being tested. The design then works by requiring that the evidence from the data for stopping the trial be strong enough so as to convince either the skeptic (in the case of concluding efficacy) or the enthusiast (in the case of concluding insufficient efficacy).

Both Thall and Simon's designs, as well as Heitjan's, explicitly make use of probability distributions for both the response proportions of the standard drug as well as the new drug. This is unlike what happens in frequentist designs in which the response rate of the standard drug is only taken into account implicitly (via the value of the pre-specified fixed target threshold). Mehta and Cain^[32] make use of a fixed-target threshold in their Bayesian approach for the early stopping of pilot studies. However they do not consider the problem of sample size determination as such, but instead address the issue of the early termination of trials with planned sample sizes that have already been determined using other methods.

Huang et al.^[28] uses short-term response information to adaptively randomize subjects to treatment arms. The design is suitable for trials for which the primary endpoint is to evaluate survival outcomes, in particular of progression-free survival. They model the relationship between the short-term response and long-term survival using a Bayesian model, first using prior clinical information and then dynamically updating the model using accruing data from the trial. The trial will terminate once the pre-specified threshold probability or the maximum number of patients is reached, and hence there is no explicit sample size calculation at the design stage.

Here we discuss two variants of a Bayesian design for phase II clinical trials. As with the designs of Thall and

Simon, and of Heijttian, but in contrast to many of the other Bayesian designs proposed,^[25–27, 33–35] these designs do not require the specification of a loss or utility function. However, unlike them, they allow for the specification of a prior distribution for the response rate of the new drug and not one for the standard drug. This is intended to bring the designs closer to the more familiar frequentist designs and hence facilitate their adoption into clinical research practice.

The Tan-Machin designs we describe are two-stage designs. In such designs n patients are recruited to Stage 1 and (possibly) a further $N - n$ to Stage 2. However, we recognized when proposing these new designs that there are practical constraints, arising from experience with other designs, which need to be considered. These suggest that designs with Stage 1 of fewer than 5 patients are unlikely to be ever adopted in practice, and often realistic bounds to the lower and upper limits to the total study size, N , are set. In what follows, we have set these to 10 and 90 patients respectively.

SINGLE THRESHOLD DESIGN

We consider the first variant of Tan-Machin design, which is referred to as the Single Threshold Design (STD). Let R_U be the target response rate for any new drug and π_{prior} be the anticipated response rate for the drug being tested. Furthermore, let λ_1 and λ_2 (with $0 < \lambda_1 < \lambda_2 < 1$) be the minimum desired threshold probabilities, at the interim stage and at the end of the trial respectively, that the true response rate, π , exceeds R_U . We note that λ_1 and λ_2 replace the frequentist type I and type II error probabilities.

The design then determines the sample sizes for the trial based on the following principle. Suppose that the trial was to be conducted and that x_1 and x_2 were the resulting data obtained from Stage 1 and Stage 2 respectively. (Note that as no actual data has yet been observed from the trial, x_1 and x_2 at this point represent the hypothetical data that we assume would arise from the trial.) Now, suppose also that the (hypothetical) response proportion underlying x_1 and x_2 is just larger than the pre-specified R_U , that is, $R_U + \varepsilon_U$, where ε_U is some pre-selected small value (say 0.05). We then want the smallest overall sample size, N , that will enable the posterior probability at the end of the trial, $\Pr(\pi > R_U | x_1, x_2)$, to be at least λ_2 . At the same time, we also want the Stage 1 sample size n to be large enough so that the posterior probability at the end of Stage 1, $\Pr(\pi > R_U | x_1)$ is at least λ_1 . We want the smallest such value for n .

Once the sample sizes have been determined and the trial started, the n patients are recruited into Stage 1 of the trial. At the end of Stage 1, the posterior probability, $\Pr(\pi > R_U | x_1)$, is then evaluated. Note that x_1 now represents the actual data from Stage 1 of the trial, and not the hypothetical data used in the sample size determination. If $\Pr(\pi > R_U | x_1)$ is less than λ_1 , the trial terminates on the grounds that there is insufficient potential that the drug

will be found efficacious enough to be recommended for testing in a phase III trial. In addition, if the number of responses in Stage 1 are so low to the extent that, even if all the patients to be recruited in Stage 2 were to be responders, the final probability of θ exceeding R_U will still not exceed λ_2 , the trial would also terminate.

If neither of the above events occur, a further $N - n$ patients would be recruited into Stage 2 of the trial. The final posterior distribution, $\Pr(\pi > R_U | x_1, x_2)$ would then be evaluated. If this is found to be less than λ_2 , the trial would conclude that the drug is insufficiently efficacious to justify proceeding for phase III testing. Otherwise, if $\Pr(\pi > R_U | x_1, x_2)$ is greater than or equal to λ_2 , progression to a phase III trial would be recommended.

Prior Distribution

Assume that there is relatively little information available regarding the efficacy of the drug in treating the particular cancer in question. In such a situation, it would be appropriate to utilize a vague prior distribution in the trial design. In particular, we make use of a vague Beta distribution, which takes values between 0 and 1. (The case of having informative prior distributions is discussed by Mayo and Gajewski.^[3,4])

Following the form of the optimistic prior suggested by Heijttian,^[24] except that we center our prior on π_{prior} rather than R_U , we construct a vague Beta (α, β) prior distribution with parameters: $\alpha = \pi_{\text{prior}} + 1$, and $\beta = (1 - \pi_{\text{prior}}) + 1$. This represents weak prior information with mode at π_{prior} . Such a prior distribution is sufficiently vague to allow for the possibility that π may take any value in the range $0 < \pi < 1$, although the most likely value is π_{prior} .

Computational Algorithm and Sample Sizes

Before the start of the trial, the investigator is asked to provide, for the type of patients under investigation and in the knowledge of currently available drugs, the values of R_U , π_{prior} , λ_1 and λ_2 . The investigator may also provide the value of ε_U or alternatively, use the default value of $\varepsilon_U = 0.05$.

The algorithm then sets up a vague Beta prior distribution based on the elicited value of π_{prior} . Following this, a search is made for the smallest $N \geq 10$ that satisfies $\Pr(\pi > R_U | x_1, x_2) > \lambda_2$, where here, x_1 and x_2 are hypothetical data with a total sample size of N and a response proportion of $R_U + \varepsilon_U$.

To carry out this search, the algorithm starts with $N = 9$ and determines whether the condition $\Pr(\pi > R_U | x_1, x_2) > \lambda_2$ is satisfied. If so, it proceeds to test whether the condition $\Pr(\pi > R_U | x_1) > \lambda_1$ is met for $n = N - 5 = 4$. If this condition is also met, the algorithm terminates and concludes that the optimal N is less than 10.

Assume that the algorithm does not terminate at this point. It then considers $N = 10$ and calculates the corresponding value of $\Pr(\pi > R_U | x_1, x_2)$. If this exceeds λ_2 , the

algorithm proceeds to search for the optimal n (see next paragraph). Otherwise, it moves on to consider $N + 1$ and as before evaluates whether $\Pr(\pi > R_U | x_1, x_2)$ exceeds λ_2 . This process continues until a suitable N is found or until the maximum pre-specified value of N ($= 90$) is reached. If no suitable N is eventually found, the algorithm terminates with the conclusion that the recommended sample size exceeds $N = 90$.

Now, supposing that a suitable N in the range $10 \leq N \leq 90$ has been found. A further search is then made to identify the smallest n between 5 and $N - 5$ that satisfies $\Pr(\pi > R_U | x_1) > \lambda_1$. This is done in the same way as for the search over N , except that we now want to satisfy the condition that $\Pr(\pi > R_U | x_1) > \lambda_1$ instead. If no such n is found in the range $5 \leq n \leq N - 5$, the algorithm rejects this value of N and moves on to $N + 1$ in the process of searching for the next smallest value of N which satisfies $\Pr(\pi > R_U | x_1, x_2) > \lambda_2$.

The algorithm will eventually arrive at one of 4 possible outcomes: (a) it finds and outputs the recommended n and

N values, in the desired ranges, (b) it concludes that $N < 10$, (c) it concludes that $N \geq 10$ but $n < 5$, (d) it concludes that either $N \geq 90$ or $n \geq 85$.

Sample sizes and cutoff values for a range of R_U , π_{prior} , λ_1 and λ_2 values have been tabulated. A selection of these (with $\varepsilon_U = 0.05$) are given in Table 1. For more extensive tables, see Tan and Machin.^[1]

DUAL THRESHOLD DESIGN

The Dual Threshold Design (DTD) is identical to the STD except that the Stage 1 sample size is determined, not on the basis of the probability of exceeding R_U , but on the probability that π will be less than the “no further interest” proportion, R_L . This represents the response rate below which the investigator would have no further interest in the new drug. R_L thus functions as a lower threshold on the response rate, as opposed to the upper threshold represented by R_U . The rationale behind

For each value of R_U , the first, second, and third rows correspond to $(\lambda_1, \lambda_2) = (0.6, 0.7)$, $(0.6, 0.8)$, and $(0.7, 0.8)$, respectively. The drug is rejected if the response rate is less than or equal to the fractions above. Where no fractions are given, the interpretation is as follows: “*a*”—Overall Sample Size < 10 ; “*b*”—Overall Sample Size ≥ 10 but Stage 1 Sample Size < 5 ; “*c*”—Overall Sample Size > 90 or Stage 1 Sample Size > 85 .

this aspect of the DTD is that we want our Stage 1 sample size to be large enough so that, if the trial data really does suggest a response rate that is below R_L , we want the posterior probability of π being below R_L , to be at least λ_1 . We want to find the smallest Stage 1 sample size that satisfies this criterion.

To implement the design, n patients are recruited into Stage 1 of the trial. At the end of Stage 1, the posterior probability, $\Pr(\pi < R_L | x_1)$, is evaluated. If this is found to be greater than λ_1 , the trial terminates on the grounds that the response rate of the drug is likely to have a high probability of being below the “no further interest” response proportion, R_L . Also, as for the STD, if the number of responses in Stage 1 are so low to the extent that it is not possible for final probability of θ exceeding R_U to meet the λ_2 threshold, the trial will also terminate at this point.

Otherwise, the trial proceeds to recruit a further $N - n$ patients. The final posterior distribution, $\Pr(\pi > R_U | x_1, x_2)$ is then evaluated. As in the STD, the decision as to whether to recommend further testing of the drug in a phase III trial will then depend on whether $\Pr(\pi > R_U | x_1, x_2)$ is greater than or less than λ_2 .

Prior Distribution, Computational Algorithm, and Sample Sizes

The same vague Beta prior distribution used for the STD is again used for the DTD. As for the computational algorithm, this works as follows. Before the start of the trial, values of R_U , π_{prior} , λ_1 and λ_2 need to be elicited as in the STD. (However, note that we no longer require the condition that $\lambda_1 < \lambda_2$ as in the STD.) In addition, the investigator now also needs to provide a value for R_L . Values for ε_U and ε_L ($0 < \varepsilon_L < R_L$) may also be specified or the default values of $\varepsilon_U = \varepsilon_L = 0.05$ used.

The algorithm then searches for the optimal value of N as in the STD. For each selected N , it then searches for the smallest n in the range $5 \leq n \leq N - 5$ such that, if (hypothetically) the trial data were to have a response proportion of $R_L - \varepsilon_L$, the value of $\Pr(\pi < R_L | x_1)$ would be strictly greater than λ_1 .

Sample sizes for selected values of R_L , R_U , π_{prior} , λ_1 and λ_2 using the DTD with $\varepsilon_L = \varepsilon_U = 0.05$ have been tabulated. A selection of these are given in Table 2, for the case when $R_U - R_L = 0.2$ (see Tan and Machin^[1] for a wider range of values).

Table 2 Number of Patients Required for the Dual Threshold Design With $\varepsilon_L = \varepsilon_U = 0.05$ ($R_U - R_L = 0.2$)

For each value of R_U , the first, second and third rows correspond to $(\lambda_1, \lambda_2) = (0.6, 0.7)$, $(0.6, 0.8)$, and $(0.7, 0.8)$, respectively. The drug is rejected if the response rate is less than or equal to the fractions above. Where no fractions are given, the interpretation is as follows: “*b*”—Overall Sample Size ≥ 10 but Stage 1 Sample Size < 5 ; “*c*”—Overall Sample Size > 90 or Stage 1 Sample Size > 85 .

PROBABILITIES OF EARLY TERMINATION AND EXPECTED SAMPLE SIZES

We now obtain the probabilities of early termination (PET) and the expected sample sizes (EN) of STD and DTD, given that the true response proportion, π , is $(R_L - 0.05)$. Here we note that as we are in a Bayesian framework, π does not actually have a fixed value but instead has a probability distribution. Nevertheless, for the purpose of making these computations, we assume that π has a single “true value,” $(R_L - 0.05)$. We can also view this as a probability distribution with zero variance and mean $(R_L - 0.05)$.

For the DTD, the PET is then given by $\Pr [\Pr (\pi < R_L | x_1) > \lambda_1]$, where x_1 is the data from a binomial distribution with parameters n and $(R_L - 0.05)$. For the STD, the PET is given by $\Pr [\Pr (\pi > R_U | x_1) < \lambda_1]$, where x_1 is also from a binomial distribution but with parameters n and $(R_U - 0.05)$. As for the expected sample size, this is given by $EN = n + (1 - PET)(N - n)$.

Tables 3 and 4 give the PET and EN values corresponding to the STD and DTD, respectively, with $R_U - R_L = 0.2$, $\varepsilon_L = \varepsilon_U = 0.05$ and $(\lambda_1, \lambda_2) = (0.6, 0.7)$, $(0.6, 0.8)$ and $(0.7, 0.8)$. The PET values for the STD (Table 3) are mostly above 0.7 (many above 0.9), suggesting that the design is likely to recommend stopping at the end of Stage 1, if π is really equal to $R_U - 0.05$. For the DTD (Table 4), the PET values tend to be lower, generally around 0.5. We note however, that for both the STD and DTD, the PET values depend on what we set the true π to be. Taking smaller true π values will increase the PET. As for the EN, these range from 11.1–53.9 for the STD and from 21.2–60.2 for the DTD.

We have also investigated other properties of the design, such as the variation of the sample sizes with π_{prior} , λ_1 , λ_2 and ε_U . Comparisons between Tan-Machin and Simon's optimal and minimax designs^[9] have also been made. The interested reader is referred to Tan and Machin^[1] for a detailed discussion of all these.

PHASE II TRIAL USING A TRIPLET COMBINATION: PACLITAXEL, CARBOPLATIN, AND GEMCITABINE IN METASTATIC NASOPHARYNGEAL CARCINOMA

A phase II trial on the activity of a triplet combination of paclitaxel, carboplatin, and gemcitabine in chemotherapy-naïve patients with metastatic nasopharyngeal carcinoma was conducted at the National Cancer Centre in Singapore, with patient enrollment between July 2001 and April 2003.^[2]

This trial was designed to test the hypothesis of no further interest in the regimen if the response rate (complete responses and partial responses) was as low as 60% against the alternative hypothesis of an overall response rate of 80% or greater. The Bayesian DTD design with parameters $\{R_L, R_U, \pi_{\text{prior}}, \lambda_1, \lambda_2\} = \{0.6, 0.8, 0.8, 0.65, 0.7\}$ was used giving rise to a required Stage 1 sample size of $n = 19$ and a possible total sample size of $N = 32$ patients.

At the end of Stage 1, the data collected from the first $n = 19$ patients were used to update the prior distribution, based on the value of $\pi_{\text{prior}} (= 0.8)$ specified for the trial.

The probability that π was less than $R_L = 0.6$ was evaluated and under the DTD, the trial was only to proceed to Stage 2 if $\Pr(\pi < R_L | x_1)$ is less than λ_1 .

Eighteen responses (out of the 19 patients) were reported at the end of Stage 1. Based on this data, it was found that $l_1 = \Pr(\pi < R_L | x_1) = 0.0005 < \lambda_1 (= 0.65)$. Moreover it remained possible for the trial to eventually conclude “success” because should all the 13 Stage 2 patients be responders, we would have $\Pr(\pi > R_U | x_1, x_2) = 0.9931$, which would exceed λ_2 . Hence the Stage 1 criteria of the DTD to proceed to the next stage was met, and the trial proceeded to Stage 2.

At the end of Stage 2, a further 7 responses were reported, resulting in a total of 25 responses (out of the total 32 patients). This is used to further update the probability distribution of π to give a final posterior probability of $u_2 = \Pr(\pi > R_U | x_1, x_2) = 0.37$. Since $u_2 = 0.37 < \lambda_2 = 0.7$, this suggests that the triplet combination is not quite as promising as was hoped before the start of the trial. We note, however, that while $u_2 = \Pr(\pi > R_U | x_1, x_2)$ is only 0.37, $l_2 = \Pr(\pi < R_L | x_1, x_2)$ is still smaller than 0.65 at 0.0167. Thus, we clearly also cannot conclude “no further interest” in the triplet combination.

Now assume, for the purpose of illustration, that the STD was instead used to design the trial, with a hypothesis to test for an overall response rate of 80% or greater, with similar prior expected response rate, Stage 1 and 2 threshold probabilities of 0.8, 0.65 and 0.7, respectively. The STD design with parameters $\{R_U, \pi_{\text{prior}}, \lambda_1, \lambda_2\} = \{0.8, 0.8, 0.65, 0.7\}$ would require a Stage 1 sample size of $n = 24$ and a total sample size of $N = 32$ patients. Assuming that the study was conducted using the STD, at the end of Stage 1, the data collected from the first 24 patients would be used to update the prior distribution, based on the value of π_{prior} ($= 0.8$) specified. The probability that π is greater than $R_U = 0.8$ would then be evaluated.

The actual data from the trial showed that there were 22 responses out of the first 24 eligible patients. Based on this data, it was found that $u_1 = \Pr(\pi > R_U | x_1) = 0.8965$. Since $u_1 = 0.8965 > \lambda_1 = 0.65$, then the response rates at Stage 1 would have also satisfied the Stage 1 criteria of the STD to allow the trial to proceed to Stage 2.

At the end of Stage 2, based on the result of 25 responses (out of the total 32 patients), the updated probability distribution of π would give a final posterior probability of $u_2 = \Pr(\pi > R_U | x_1, x_2) = 0.37 < \lambda_2 (= 0.7)$ and conclude that the triplet combination is not quite as promising as anticipated at the start of the trial. Note that this is the same calculation as for the DTD.

It can be seen that for this particular trial, the initial very encouraging results seen in patients recruited in the first stage of the trial were generally not reproduced in patients recruited into the second stage.

ADAPTATIONS OF THE DESIGNS

A number of authors have proposed Bayesian phase II designs that were adaptations to the original design proposed by Tan and Machin. Mayo and Gajewski^[3] had in their first adaptation to the design extended the sample size calculations to include informative prior distributions. The informative prior distributions were defined based on several strategies. These strategies allow researchers with a pessimistic or optimistic prior to be involved in the sample size decision-making. Four approaches to constructing the informative prior were discussed in the article. Sample size was then determined using the same principles as in Tan-Machin of calculating a posterior probability that the true response rate will exceed a pre-specified target. However, unlike the Tan-Machin design, the sample size calculations were for single-stage phase II trials and hence did not have analogous single threshold and dual threshold variants.

In Gajewski and Mayo's second adaptation,^[4] they incorporated the use of a mixture of informative priors. The mixture would be defined based on several sources of information, and could also be constructed from a combination of pessimistic and optimistic opinions from

clinicians. Similar to their earlier adaptation, the sample size calculation is for single-stage phase II trials.

Sambucini^[5] introduced a "predictive version" of the STD design. The proposed method is motivated by the uncertainty surrounding the observations to be (but not yet) made and wanting to take that into account in the sample size calculation. It utilizes a design prior with mode greater than the target value to compute the prior predictive distribution of the data and a non-informative analysis prior to obtain the posterior probabilities of the treatment efficacy. The two-stage sample sizes are determined based on the criteria that the probabilities, computed with respect to the prior predictive distributions of the data, of getting the posterior probability greater than or equal to λ_1 and λ_2 (the STD thresholds) is greater than or equal to two additional thresholds, γ_1 and γ_2 respectively. As such, the design requires a larger number of design parameters to be specified than the original STD and differs from the STD in that the optimal second stage sample size and cutoff level depends on the first-stage optimal sample size and cutoff level.

DISCUSSION

We believe that Bayesian methods provide a good alternative to frequentist approaches for phase II clinical trials and have much to offer to the design, monitoring, and analysis of such trials. They allow for the incorporation of relevant prior information and the presentation of the trial results in a manner that seems more intuitive and helpful than what is obtained from a frequentist analysis. However, one of the main reasons why Bayesian methods are not in common use is because of their unfamiliarity to investigators and the perceived difficulty of implementation. However, the Tan-Machin designs are relatively simple compared to many of the other Bayesian phase II designs in the literature.

These designs are presented in a way that should be reasonably familiar to anyone who has had experience working with frequentist designs such as the Simon two-stage designs. As with Simon's designs, the investigator needs to specify for the STD appropriate values for R_U and (for the DTD) R_L . They also need to specify λ_1 and λ_2 values (as opposed to type I and II errors). Finally they need to specify a value for π_{prior} , their prior anticipated response rate for the new drug. This is a single value that will "automatically" form the basis of a vague prior. Thus there is no need to elicit a full prior distribution (although it is straightforward to adapt the design for use with, for example, an elicited informative Beta prior). Once all these values have been specified, the design establishes Stage 1 and overall sample sizes for the trial. Other variables, such as ε_U and ε_L can also be specified if desired, but it is usually sufficient to use the default values for these.

The choice of λ_1 and λ_2 values will clearly have a strong impact on the recommended sample sizes (in the same way that the choice of type I and type II error values will affect frequentist designs). In Tables 1 and 2, we make use of $(\lambda_1, \lambda_2) = (0.6, 0.7)$, $(0.6, 0.8)$ and $(0.7, 0.8)$ values. These were chosen on the basis that they gave rise to sample sizes which generally covered a similar range to those recommended by the commonly used Simon designs. Choosing smaller threshold values would result in smaller sample sizes. However, this could potentially be at the cost of having a design that has an unreasonably low probability of detecting a true effect (that is, the distribution of π is mostly above R_U or is below R_L) when the data does actually suggest this. On the other hand, using threshold values that are too high could result in sample sizes that are too large to be of practical value. There is thus a tradeoff between wanting a small sample size for practical reasons, while at the same time, ensuring that the corresponding λ_1 or λ_2 value is not too low.

The STD and DTD designs have been prospectively used in actual clinical trials. In particular, the STD has been used in the design of a phase II study to evaluate the use of Interferon- α for recurrent WHO grade 1 intracranial meningiomas^[36] and the DTD has been used in the design of a phase II clinical trial to evaluate the use of a triplet combination of paclitaxel, carboplatin, and gemcitabine in metastatic nasopharyngeal carcinoma conducted at the National Cancer Centre in Singapore.^[2]

We have utilized the latter trial^[2] to illustrate the use of the DTD. We have also applied the STD in that example by removing the no further interest threshold, R_L , which is only applicable in the DTD setting, to demonstrate the different objectives that the two variants of the design serve. Both the STD and DTD recommended that the trial should carry on to the second stage. However, the STD is concerned with ensuring, at the interim stage, that the final response rate of the drug has a reasonable probability of exceeding the target R_U at the end of the trial. On the other hand, the DTD is concerned at the interim stage in making sure that the final response rate is not lower than the no further interest threshold, R_L . The final results of the trial (designed using DTD) concluded that while there was insufficient evidence that the response rate exceeded R_U , it was also clear that the rate was not below R_L . Thus the DTD have correctly recommended that the trial moved on to the next stage. The STD however, did not recommend that the trial be terminated after Stage 1, and this was largely due to the initial encouraging results seen in first stage that were not reflected in the second stage.

Alongside that for other commonly used phase II designs, interactive and user-friendly sample size calculation software^[37,38] has been developed to implement the Tan-Machin designs. Adaptations of the basic designs to address two primary (binary) endpoints, and an endpoint that is ordinal, is currently in progress. The first arises because both efficacy and toxicity need to be considered

simultaneously when a new cancer therapy is being developed. The latter arises in situations concerning patients with retinoblastoma in which one or both eyes may be involved, when response could be in neither, one, or both organs.

Bayesian Estimate: Concordance Correlation Coefficient

Dai Feng, Richard Baumgartner, and Vladimir Svetnik

Biometrics Research, MRL, Rahway, New Jersey, U.S.A.

Abstract

Concordance correlation coefficient (CCC) is one of the most frequently used and reported scaled indices of agreement. There have been several frequentist methods proposed to estimate the CCC. Thus, several questions pertaining to the Bayesian estimate of the CCC naturally arose. In this entry, we aimed at answering the following questions: Is there any added value of a Bayesian approach when compared to frequentist methods? How is a Bayesian estimate of the CCC executed? Are there any potential limitations of Bayesian approaches and what are the possible solutions? Most of the Bayesian methods discussed in the entry were implemented in a package *agRee* available from the Comprehensive R Archive Network.

Keywords: Concordance correlation coefficient; Bayesian; MCMC; Accommodation of covariates; Missing values and multiple replications; Model diagnostics and comparison.

INTRODUCTION

The need for assessment of agreement between observers is ubiquitous in a wide variety of substantive fields.^[1] Note that observer is a generic term, and in the drug development environment, it could refer to measurement method, test, assay, device, etc. There are, in general, three approaches for measuring agreement—descriptive tools, unscaled agreement indices, and scaled agreement indices.^[1] Among them, a widely used scaled index is the concordance correlation coefficient (CCC).

The CCC originally proposed by Lin^[2] measures the variation of linear relationship between readings from two observers from the 45° line through the origin. For pairs of samples (y_{i1}, y_{i2}), from $i = 1, 2, \dots, n$ subjects, the expectation of the squared difference $E[(Y_{i1} - Y_{i2})^2]$ measures the degree of concordance between two observers. Furthermore, the value of $E[(Y_{i1} - Y_{i2})^2]$ is transferred to make it scaled between -1 and 1. The larger the CCC value, the better the agreement. Hereafter, an uppercase Y (with subscript) is used to denote a random variable (or vector) and a lowercase y (with subscript) is used to denote the corresponding sample of Y .

The concept of CCC was extended to multiple observers for data without or with replications^[3–6] and to data with repeated measures from two or multiple fixed or random observers.^[7–11] These extensions usually ensue from using different analysis of variance models. Inference is typically based on the normality assumption or performed using semiparametric generalized estimating equations or non-parametric approaches.^[1,6]

Given several frequentist methods having been proposed to estimate the CCC, a natural question of a need for another Bayesian approach and its utility arose. What would be the additional benefits of the Bayesian methods and how could the Bayesian estimation be carried out? Are there potential limitations and challenges with the Bayesian methods and what are the possible solutions? This entry is aimed at answering these questions. Section “Motivation for Bayesian Estimate of the CCC” presents the motivation for the Bayesian estimate of the CCC. Section “How to Execute the Bayesian Estimate of the CCC” describes the details of Bayesian estimation. Section “Potential Limitations and Future Research for the Bayesian Estimate of the CCC” focuses on the potential issues with the Bayesian approaches and discusses possible solutions and future research topics.

MOTIVATION FOR BAYESIAN ESTIMATE OF THE CCC

A series of Bayesian methods for the estimation of the CCC were proposed and investigated.^[12–15] A motivating example in the study by Feng, Baumgartner, and Svetnik^[15] was from insomnia drug development. The gold standard for obtaining sleep measurements is through a polysomnography (PSG) study whereby a subject sleeps in a specially equipped lab, in which the brain's electrical activity, along with multiple other signals, is measured with a number of sensors attached to the subject's head, face, and body. Collected signals, or waveforms, are then

analyzed and each 30-second epoch of a subject's sleep (typically 8-hour) is attributed to (or scored as) one of five states (four for sleep and one corresponding to wake^[16]). Once scoring is completed, various summary measures of sleep are calculated.

The PSG scoring by visual analysis, though considered a gold standard for PSG data processing, is usually quite tedious and takes huge amount of time. There have been efforts made to develop semiautomated or automated procedures for PSG scoring, which would provide objective outcomes and greatly reduce variability, time, and cost of the sleep clinical trials. Thus, evaluation of agreement between the gold standard manual PSG scoring and these procedures is of paramount importance in the development of sleep drugs.

A widely used continuous measurement of sleep quality is total sleep time (TST), the total amount of time in minutes spent at different sleep stages. In a clinical study detailed in Svetnik et al.,^[17] PSG recordings from 82 subjects were collected during two nights of sleep, one under placebo, and one under drug (zolpidem, 10 mg) treatment. For each recording, different methods were used to provide the TST scores. The data from two observers of the drug arm, the semiautomatic procedure WideMedPartial versus manual, are plotted in Fig. 1.

The sample skewness of the TST from manual and WideMedPartial was -2.50 and -2.70 , respectively. The sample kurtosis of the TST from manual and WideMedPartial was 8.47 and 9.11 , respectively. These data are obviously skewed to the left and heavy tailed. To our knowledge, there was no discussion before Feng, Baumgartner, and Svetnik^[15] that focused on this type of data in the literature of the CCC (investigation of the right-skewed data was presented in Carrasco et al.^[18]). In Feng, Baumgartner, and Svetnik,^[15] the issue was addressed

using multivariate skew normal (MVSN) and multivariate skew t (MVST) distributions to accommodate various type of data structure—symmetric or skewed to the left/right and light or heavy tailed.

Another important question that relates to the estimation of CCC is the performance of non-parametric methods such as bootstrap.^[19] Can they provide accurate estimate, for example, when the data is left skewed and heavy tailed? A simulation study in Feng, Baumgartner, and Svetnik^[15] showed that, in different scenarios for bivariate skew t distributions (BVSTs), the Bayesian approach tended to provide more accurate coverage probabilities. For completeness, the results of Feng, Baumgartner, and Svetnik^[15] study on the Bayesian and bootstrap methods, respectively, are presented in Tables 1 and 2. The discrepancy between the actual and the nominal coverage from using the U-statistics as in King and Chinchilli^[20] was even larger and the corresponding results are not shown here. When data are from bivariate t -distributions, Feng, Baumgartner, and Svetnik^[13] conducted a thorough investigation on the difference between the bootstrap distribution and sample distribution and demonstrated that the bootstrap estimates tended to be biased downward. The details on Bayesian estimation (including the treatment of BVST) are presented in section “How to Execute the Bayesian Estimate of the CCC.”

Can data be transformed and then treated as normal and the CCC be estimated? The coverage probabilities for the CCC after taking the Box–Cox transformation^[21] of the left-skewed and heavy-tailed data and treating them as normally distributed (estimated by variance components method proposed by Carrasco and Jover^[22]) are shown in Table 3. The results were inferior to that from the Bayesian approach.

Fig. 1 Histograms and scatter plot of measurements of the TST in minutes from manual and WideMedPartial

Note: The different simulation scenarios had the parameter $\nu = 5$ and $\mu_1, \mu_2, \sigma_1, \sigma_2$ with different values and various combinations of $\rho_{12}, \delta (= \delta_1 = \delta_2)$ values and sample sizes.

In general, the Bayesian method has advantages such as obeying the likelihood principle and having a natural interpretation of confidence intervals (known as “credible sets” or “credible intervals”). The estimate of CCC can benefit from using the Bayesian approach specifically due to its capability of providing inferential quantities of any functions of parameters directly for a variety of parametric and non-parametric models without using the plug-in method and asymptotic approximation.

More detailed comparison results between the Bayesian and frequentist methods can be found in the studies by Feng, Baumgartner, and Svetnik.^[12–15] The Bayesian approaches provided very compelling results even from a frequentist point of view such as accurate coverage probabilities. In addition, the Bayesian methods could avoid less ideal situations such as increasing number of observers, subjects, or decreasing percentage of missing data leading to worse coverage. Furthermore, practically relevant issues such as accommodation of covariates and missing data and model diagnostics and comparison, were addressed coherently within the Bayesian framework. Section “How to Execute the Bayesian Estimate of the CCC” presents the details of implementing the Bayesian approach to estimate the CCC.

HOW TO EXECUTE THE BAYESIAN ESTIMATE OF THE CCC

In this section, the Bayesian estimation for a basic setup is discussed first and then the extension to address other practically relevant issues is discussed.

Estimation for a Basic Setup

A typical setup in an agreement study is that for each subject i , we have samples $\mathbf{y}_i = (y_{i1}, \dots, y_{id})$ from d observers.

When there are d observers, the CCC is defined as:

$$CCC = \frac{2 \sum_{j=1}^{d-1} \sum_{j'=j+1}^d \sigma_{jj'}}{(d-1) \sum_{j=1}^d \sigma_j^2 + \sum_{j=1}^{d-1} \sum_{j'=j+1}^d (\mu_j - \mu_{j'})^2} \quad (1)$$

where σ_j^2 and μ_j are the variance and mean of the measurements made by observer j , respectively, and $\sigma_{jj'}$ is the covariance between measurements from observers j and j' ($j, j' = 1, \dots, d \geq 2$).

In principle, it is straightforward to conduct a Bayesian estimate of the CCC. First, given certain assumptions, a likelihood function is formulated and the corresponding priors are specified. The posterior distributions of parameters in the likelihood can then be estimated using, e.g., the Markov chain Monte Carlo (MCMC) approach. Finally, the posterior distribution of function of parameters, which is the CCC in this case, and the corresponding point estimate and credible interval can be obtained.

To formulate a likelihood and facilitate the MCMC and improve mixing, data augmentation is a very effective tool.^[23] Besides the original vector of parameters $\boldsymbol{\theta}$, some latent variables $\boldsymbol{\theta}_{\text{aug}}$ are created. With the introduction of $\boldsymbol{\theta}_{\text{aug}}$,

the likelihood $f(\mathbf{y}_i | \boldsymbol{\theta})$ equals $\int f_1(\mathbf{y}_i | \boldsymbol{\theta}_{\text{aug}}, \boldsymbol{\theta}) f_2(\boldsymbol{\theta}_{\text{aug}} | \boldsymbol{\theta}) d\boldsymbol{\theta}_{\text{aug}}$.

A Markov chain $\{(\boldsymbol{\theta}^t, \boldsymbol{\theta}_{\text{aug}}^t), t \geq 1\}$ is formed and $\boldsymbol{\theta}^t, \boldsymbol{\theta}_{\text{aug}}^t$ are drawn iteratively from the respective conditional distributions.

Feng, Baumgartner, Svetnik,^[15] proposed a general Bayesian framework to accommodate various types of data structure—symmetric or skewed to the left/right and light or heavy tailed. The proposal was based on the MVS/N/MVST distributions discussed in the study by Sahu, Dey, and Branco.^[24] The density of $\mathbf{y}_i$ having a MVST distribution with parameters $\boldsymbol{\mu}, \boldsymbol{\Sigma}, \mathbf{D}$, and ν is as follows:

$$\begin{aligned} f(\mathbf{y}_i | \boldsymbol{\mu}, \boldsymbol{\Sigma}, \mathbf{D}, \nu) &= 2^d t_{d, \nu}(\mathbf{y}_i | \boldsymbol{\mu}, \boldsymbol{\Sigma} + \mathbf{D}^2) \times T_{d, \nu+d} \\ &\times \left[\left(\frac{\nu + q(\mathbf{y}_{i*})}{\nu + d} \right)^{-\frac{1}{2}} \right. \\ &\times (\mathbf{I} - \mathbf{D}(\boldsymbol{\Sigma} + \mathbf{D}^2)^{-1} \mathbf{D})^{-\frac{1}{2}} \\ &\times \mathbf{D}(\boldsymbol{\Sigma} + \mathbf{D}^2)^{-1} \mathbf{y}_{i*} \left. \right] \quad (2) \end{aligned}$$

where $\mathbf{y}_{i*} = \mathbf{y}_i - \boldsymbol{\mu}$; $q(\mathbf{y}_{i*}) = \mathbf{y}_{i*}^T (\boldsymbol{\Sigma} + \mathbf{D}^2)^{-1} \mathbf{y}_{i*}$; $t_{d, \nu}(\mathbf{y}_i | \boldsymbol{\mu}, \boldsymbol{\Sigma} + \mathbf{D}^2)$ is the density of multivariate t -distribution of a d dimension vector $\mathbf{y}_i$ with location vector $\boldsymbol{\mu}$, scale matrix $\boldsymbol{\Sigma}$, and degrees of freedom ν , respectively; $T_{d, \nu+d}(\cdot)$ denotes the cumulative distribution function (cdf) of a multivariate t -distribution for a d dimensional vector with location vector $\mathbf{0}$, scale matrix $\mathbf{I}$ (an identity matrix), and degrees of freedom $\nu + d$.

Instead of directly assigning prior distributions on parameters $\boldsymbol{\theta} = (\boldsymbol{\mu}, \boldsymbol{\Sigma}, \mathbf{D}, \nu)$ based on the density function (2), Feng, Baumgartner, and Svetnik^[15] adopted the formulation in the study by Sahu, Dey, and Branco^[24] as follows:

$$\begin{aligned} \mathbf{Y}_i | \mathbf{Z}_i, \boldsymbol{\mu}, \boldsymbol{\Sigma}, \mathbf{D}, \omega_i &\sim \text{MVN}(\boldsymbol{\mu} + \mathbf{D}\mathbf{Z}_i, \frac{1}{\omega_i} \boldsymbol{\Sigma}) \\ \mathbf{Z}_i &\sim \text{MVN}(\mathbf{0}, \mathbf{I}) \mathbf{I}(\mathbf{Z} > \mathbf{0}) \\ \omega_i | \nu &\sim \Gamma(\nu/2, \nu/2) \end{aligned} \quad (3)$$

where $\text{MVN}(\cdot)$ denotes a multivariate normal distribution, $\Gamma(\cdot)$ denotes a gamma distribution with corresponding shape and rate parameter, and $\mathbf{I}$ is an indicator function. Note that with the introduction of latent variables $\boldsymbol{\theta}_{\text{aug}} = (\mathbf{Z}_i, \omega_i)$, most of the parameters in $(\boldsymbol{\theta}, \boldsymbol{\theta}_{\text{aug}})$ have conjugate priors. The data augmentation was adopted in other proposals that used the MCMC to estimate the CCC^[13,14] as well.

Extension to Address Other Practically Relevant Issues

Practically relevant issues, including enabling incorporation of confounding covariates, handling missing data and

multiple replications (from each observer on the same subject), accessing goodness of fit of model, and conducting model comparison, can be addressed within the Bayesian framework.

For the example in Section “Motivation for Bayesian Estimate of the CCC” that studies the agreement between semiautomatic and manual procedure to measure the TST (shown in Fig. 1), there seems to be a shift of TST values depending on gender—females tended to have higher values than males (see Fig. 2 for details). How to address the case in which gender is a potential confounding covariate?

To accommodate covariates, such as gender in the previous example, the covariate effects can be added into the conditional mean of $\mathbf{Y}_i$. For example, if $\mathbf{Y}_i$ follows a MVST distribution, then considering the covariate effects, the conditional distribution of $\mathbf{Y}_i$ is as follows:

$$\mathbf{Y}_i | \mathbf{Z}_i, \boldsymbol{\mu}, \boldsymbol{\Sigma}, \mathbf{D}, \boldsymbol{\omega}_i \sim \text{MVN}(\boldsymbol{\mu} + \mathbf{X}_i \boldsymbol{\beta} + \mathbf{DZ}_i, \frac{1}{\boldsymbol{\omega}_i} \boldsymbol{\Sigma}) \quad (4)$$

where $\mathbf{X}_i$ is the design matrix for subject i and $\boldsymbol{\beta}$ is the vector of regression coefficients.

When there are multiple replications, let Y_{ijk} be the k^{th} reading for subject i by observer j and consider a model as follows:

$$Y_{ijk} = \mu_{ij} + \epsilon_{ijk} \quad (5)$$

Fig. 2 Boxplots of TST by gender from two different methods: WideMedPartial and manual

In this case, besides the original CCC, the inter-CCC among observers ($\text{CCC}_{\text{inter}}$) and intra-CCC for observer j ($\text{CCC}_{j,\text{intra}}$) could be defined as follows:

$$\text{CCC}_{\text{inter}} = 1 - \frac{\sum_{j=1}^{d-1} \sum_{j'=j+1}^d E(\mu_{ij} - \mu_{ij'})^2}{\sum_{j=1}^{d-1} \sum_{j'=j+1}^d E_1(\mu_{ij} - \mu_{ij'})^2} \quad (6)$$

$$\text{CCC}_{j,\text{intra}} = 1 - \frac{\sum_{k=1}^{k-1} \sum_{k'=k+1}^K E(Y_{ijk} - Y_{ijk'})^2}{\sum_{k=1}^{k-1} \sum_{k'=k+1}^K E_1(Y_{ijk} - Y_{ijk'})^2} \quad (7)$$

where E_1 is the conditional expectation given independence of two corresponding random variables (refer the study by Barnhart, Haber, and Lin^[1] and references therein for more details). With the introduction of latent variables, the key to solving the expectations in Eqs. 6 and 7 is computing expectation by conditioning ($E(A) = E(E(A|B))$) (e.g., refer the study by Feng, Baumgartner, and Svetnik^[13]).

To address missing observations, assuming the mechanism is ignorable—missing completely at random or missing at random, missing data could be treated as additional unknown parameters to be estimated along with the other parameters of interest and are simulated in each MCMC iteration. The missing data require no change to the basic model structure (as the data were complete) and only need to be represented in the data file (as “NA” when running Bayesian inference using Gibbs sampling (BUGS)^[25] or JAGS^[26]).

To assess the goodness of fit of posited Bayesian model to data, a widely used method is the posterior predictive approach. A reference distribution (with corresponding tail-area probabilities) for any test statistic^[27] can be constructed. For example, refer the study by Feng, Baumgartner, and Svetnik,^[14] in which not only the classical χ^2 but an order statistic as discrepancy measures was also used for goodness-of-fit assessment.

To select a model from several candidates, one method is to use the deviance information criterion (DIC) as in the study by Spiegelhalter et al.^[28] DIC is a generalization of the Akaike information criterion (AIC) and is also related to Bayesian information criterion (BIC). Models with smaller DIC should be preferred to models with larger DIC. In the study by Feng, Baumgartner, and Svetnik,^[15] a model based on the MVST assumption fitted the data illustrated in Fig. 1 better than several other parametric models considered.

POTENTIAL LIMITATIONS AND FUTURE RESEARCH OF THE BAYESIAN ESTIMATE OF THE CCC

Among the proposed Bayesian estimate of the CCC, a parametric distributional assumption underpins each model. The less appropriate the assumption, the worse the results. For example, in the study by Feng, Baumgartner, and Svetnik,^[14] when the variation of the data was dominated by random error, the bootstrap outperformed

the Bayesian approach. The goodness-of-fit of each model can be checked and based on the DIC, different distributional assumptions can be compared to each other. However, there might be other parametric models beyond consideration that fits the data even better. A more accurate estimate of the CCC may be obtained through some non-parametric Bayesian approaches. This warrants further investigation given especially that non-parametric Bayes would require a relatively large sample size that is uncommon, e.g., in proof-of-concept agreement studies in early drug development.

Vague conjugate priors were typically used for the Bayesian estimate of the CCC. The Bayesian paradigm allows for a straightforward adoption of informative priors in cases when there is available prior knowledge or information related to the CCC. Using conjugate priors, the point estimates of parameters are estimated from the historical data and the hyperparameters based on these estimates and the strength of belief are specified. In an agreement study, a typical setup is that a gold standard already exists and the question is whether measurements from a “new” approach can be used interchangeably. Therefore, there is often accumulated knowledge about the gold standard but limited information on the “new” approach.

As an alternative to the simple vague prior, an “objective prior” could be a better choice in terms of both appealing statistical concept and optimal property (such as probability matching property).^[29] The performance of using Jeffreys prior in the Bayesian estimate of the CCC for normally distributed data was investigated in the study by Feng, et al.^[12] Further studies on the topic are required especially in small sample size cases.

Compared to the frequentist approach, the Bayesian estimate of the CCC may demand a higher computational cost. This limitation, however, is becoming less important. First, the iterative simulation based on conditional distributions is not always necessary to conduct a Bayesian analysis. For example, when there are only two raters, under normal assumption and using the Jeffreys prior, it is straightforward to obtain independent samples from the posteriors (without using Gibbs sampling or other computationally intensive sampling methods) and hence are fast to compute. Second, a frequentist approach may require more time than originally thought. For example, although Efron and Tibshirani suggested that 1000 resampling is enough for bootstrap confidence intervals construction,^[19] 10,000 resamples were argued to be necessary for more accuracy.^[30] Finally, with the constant advancement of computing tools and availability of powerful Bayesian sampling engines such as BUGS and JAGS, the computation time is often not a concern for the Bayesian estimate of the CCC, given the relatively simple model adopted on small size of data. Most of the proposed Bayesian methods for the CCC estimation were implemented in a R^[31] package “agRee.”^[32]

The package calls internally JAGS or BUGS to run the MCMC, when necessary.

The Bayesian estimate of the CCC has been applied to continuous data. As a topic for further research, Bayesian approach could be developed to handle categorical and ordinal data based on the Bayesian generalized linear mixed models.

Abstract

This entry discusses some applications of Bayesian approaches in meta-analysis, the steps involved in a meta-analysis, computer implementation of Bayesian models for meta-analysis, extensions to the simple Bayesian model, and dealing with publication bias in the Bayesian framework.

INTRODUCTION

Meta-analysis refers to the collection and subsequent statistical analysis of results from numerous studies. The purpose of a meta-analysis is to arrive at an overall conclusion about an issue of interest based on the available data. Meta-analysis has a long history, but it has enjoyed a surge of interest and corresponding rapid methodological development in the past two decades. Philosophical and practical problems surround the combination of studies with discrepancies in aims, study designs and quality, sampling frames, populations, and reported information. Other concerns include dealing with studies of small sample size or with peculiar results, inclusion of predictors at study level, methods by which results are updated as new information is available, and accounting for the impact of other biases because of publication, selection, and so on. A Bayesian approach to meta-analysis has been advocated as a way to address many of these issues. A Bayesian model describes the structural relationship between data and unknown parameters, whereby both data and parameters are considered random variables with uncertainty. The full posterior distributions of parameters borrow strength from all studies and enable direct inference regarding probabilities about expectations and, perhaps more notably in a pharmacology context, comparisons such as the probability with which subjects receiving a particular medication are better on average recovery, symptom level, or survival, than those on an alternative medication. Moreover, by their construction, these distributions are not confined to “usual” (normal) representations or based on asymptotic assumptions, and give substantially more information than single point estimates.

The article begins with a description of some applications of Bayesian approaches in meta-analysis. The steps involved in a meta-analysis are discussed next, followed

by a description of Bayesian models for meta-analysis and selection of prior distributions. Computer implementation of Bayesian models for meta-analysis next, followed by extensions to the simple Bayesian model and dealing with publication bias in the Bayesian framework.

APPLICATIONS OF BAYESIAN METHODS IN META-ANALYSIS

Meta-analysis is among the most fundamental methods used in clinical research. Integration of results from multiple studies is linked with increased power and precision of estimated effects with the potential for clarification of contentious findings, and can be of especial benefit for studies of small sample size that tend to be linked with non-statistically significant effects because of low power. Results can also aid in constructing hypotheses for future tests in situations involving conflicting results, and provide knowledge in terms of how to better design future studies.

Meta-analysis has a long history, but it has enjoyed rapid development in the past two decades due in part to the rapid growth in research literature^[1] and expanding interest in this technique in a wide range of disciplines. Moreover, meta-analysis is an integral part of evidence-based practice, which is becoming a mainstay of many professions, particularly in medicine.^[2]

Meta-analysis is often applied to studies that involve clinical trials, due in part to government requirements via the pharmaceutical benefits advisory scheme. Meta-analysis is used to examine clinical trial information and to support clinical guidelines, to compare newly developed medications with alternative medications or placebos, to assess vaccine effectiveness, and to make decisions regarding health policies.^[3] The growing popularity of

meta-analysis has engendered commensurate discussion and critical review of the general appropriateness and validity of these methods and associated inferences.^[3–7]

A Bayesian approach to meta-analysis has been advocated as a way of addressing many of these issues.^[8] A landmark paper by DuMouchel and Harris^[9] introduced a Bayesian hierarchical model to synthesize data from five study types that assess the effects of exposure to nine environmental agents on lung cancer risk in both humans and animals. The combination of differing design types has also been demonstrated by many authors, including Dominici et al.^[10] for open and closed studies that deal with different treatment regimes for migraines, described further below; and Higgins and Whitehead^[11] demonstrate methods that can be applied to studies based on randomized control trial (RCTs) with differing interventions as the control, features that cannot typically be incorporated into a meta-analysis. The process of expressing uncertainty about parameters through prior distributions has been explored by Sutton and Abrams,^[12] and methods for quantitative updating of treatment effect assessments as data are collected have been proposed by Larose and Dey,^[1] among others. Through an example involving a meta-analysis of studies concerning breast cancer therapy, Berry et al.^[12] address problems of lacking exchangeability within and among studies, of multiple variables, and of acceptance of results from meta-analyses by practitioners.

An application considered by Sun and Suresh^[13] concerned combining results from several studies that assess efficacy of an antihistaminic drug for both seasonal allergic rhinitis, otherwise known as hay-fever, and perennial allergic rhinitis, which is an allergy unrelated to time of year. Contrary to a classical meta-analysis, which assumes exchangeability of treatment benefit among studies, exchangeability in this application is assumed only between studies with the same type of rhinitis, thus enabling the treatment benefit distribution to vary with differing rhinitis types. Prior information about disease differences with regard to treatment effect was quantified and included in the model. Covariates can also be included by generalizing the model. This may reduce heterogeneity by allowing more specific therapeutic recommendations. The study reported by Dominici et al.^[10] combined results from studies of headache treatment, which were presented in numerous ways, including as continuous effects for each treatment, as effectiveness differences for pairs of treatments, or as two-by-two contingency tables for dichotomous responses. The majority of studies were small clinical trials reporting conflicting results about treatment effectiveness. A Bayesian hierarchical random effects model for meta-analysis of grouped studies was proposed to enable an explanation for heterogeneity between studies and study types.

The logic that underlies any Bayesian approach is as follows: The data enter the model via the likelihood. A likelihood, by definition, is the probability, given model parameters, of observing the data of interest. Information

about parameters, independent of the data, is expressed through prior probability distributions that represent the uncertainty about these unknown variables. Priors can be based on a review of relevant literature, on previous phases of the same study or on the researcher's own subjective beliefs. Alternatively, they can be "vague" or "uninformative," representing little or no prior opinion and allowing all information to come from the data. These components are combined using Bayes' theorem, resulting in a joint posterior probability distribution for the unknown variables. The posterior is a revision of prior beliefs regarding parameters after having observed the data.^[14] All subsequent inferences about parameters are based on the posterior distribution.

The full posterior distributions of parameters "borrow strength" from all studies^[14] and enable direct probabilistic inference about expectations and, perhaps more notably in a pharmacology context, comparisons such as the probability with which subjects receiving a certain medication are better on average symptom level than those receiving an alternative medication. As stated in section "Introduction," these distributions give substantially more information than single point estimates. For example, a single measure cannot adequately act as a summary when a parameter's posterior distribution is very skewed. The posterior probability distribution can further be used as a prior when assessing new data in the Bayesian framework.^[14, 15] Predictions from the model can be made through posterior predictive distributions, again giving full probabilistic information about these forecasts.^[16]

STEPS IN A BAYESIAN META-ANALYSIS

Regardless of the paradigm adopted, any meta-analysis involves several steps. These include defining the research question, defining the outcome, defining the studies to collect, selecting the studies, obtaining required information from studies, developing the model, determining the computational method, interpreting results, and assessing sensitivity of the model. An additional step required under the Bayesian paradigm is the expression of various kinds of uncertainty in the model and the incorporation of these via the construction of prior distributions. These steps are now discussed in more detail.

The first step, prior to undertaking the meta-analysis, is to develop a research question. Part of this will include identification of outcomes. The outcomes for each study that form the data for the meta-analysis depend on both the required inferences from the meta-analysis and the type of data. For binary data, three common outcomes are risk difference, relative risk, and odds ratio. For continuous data, the mean with the associated standard error for each study is a potential outcome. The estimated effect size may be used if this is more commonly reported or if studies are of differing designs.

It is imperative in meta-analysis to identify both published and unpublished studies applicable to the relationship of interest.^[17,18] To obtain meaningful answers from the meta-analysis, however, criteria need to be set a priori about studies that will be considered for a meta-analysis. These criteria will depend on whether only refereed or published studies will be included (because of the perceived quality and validity of the reported results) or whether all studies will be included (thus reducing potential publication bias). The search for relevant studies should include database and Internet searches, scanning references of related manuscripts and reports, and reports from funding sources and pharmaceutical companies. If primarily published studies are included then it is imperative that the potential influence of unpublished studies is tested for. Although studies are not regarded as identical in that they are sampled from the same underlying population, they should be at least comparable^[19] on outcome and design or incompatibilities should be described in the model. For each study, the agreed outcome must be either reported or able to be calculated. Most commonly, this includes an effect size estimate as well as the corresponding standard error.

Formation of Bayesian models and computation methods are described below. Importantly, these steps should be followed by a sensitivity analysis of the model construction, priors, input data, and possible biases because of publication,^[16] selection, and so on.

BAYESIAN MODELS FOR META-ANALYSIS

Simple Hierarchical Model

The following notation will be used throughout this article. The study number will be denoted by i , and the number of studies by k , where $i = 1, \dots, k$. The true underlying effect in study i is denoted by θ_i , and the vector of true effects across all studies by $\theta = (\theta_1, \dots, \theta_k)'$. The observed effect from study i is denoted by Y_i , and the vector of observed effects by $Y = (Y_1, \dots, Y_k)'$. Variation in the i th study of the summary statistic (within-study variance) is denoted by σ_i^2 , and the corresponding precision by τ_i , where $\tau_i = 1/\sigma_i^2$. If all k studies are exchangeable, a fixed-effects model assumes all the θ_i to be equal, so that all studies are random draws from a single population. A random-effects model assumes that each θ_i is a sample from a population of effects with common mean μ . In other words, $E(\theta_i) = \mu$ with an associated variance ω^2 reflecting the between-study heterogeneity. The hyperparameters, μ and ω^2 , can also be given prior distributions to reflect the degree of uncertainty in their value. This simple random-effects model is depicted in Fig. 1. Note that Fig. 1 is similar to that produced by Liermann and Hilborn,^[20] but the notation differs accordingly.

Related meta-analysis models have been developed by various authors in the last 15 years, based on early work

Global parameters	μ, τ^2	$P(\mu), P(\omega^2)$
Study-specific parameters	$\theta_1 \theta_2 \dots \theta_k$	$P(\theta_i \mu, \omega^2)$
Data	$Y_1 Y_2 \dots Y_k$	$P(y_i \theta_i \sigma_i^2)$

Fig. 1 Simple hierarchical Bayesian model with three levels of random variables: global hyperparameters μ and τ^2 representing the overall mean effect and corresponding variance, respectively, study-specific parameters θ_i and σ_i^2 , and data Y_i . Bayesian analysis seeks to discover a joint posterior distribution of θ_i and μ , given the data

by DuMouchel and Harris,^[9] DuMouchel,^[21] Carlin,^[19] Biggerstaff, Tweedie, and Mengersen,^[5] Hasselblad and McCrory^[22] and references therein, Smith, Spiegelhalter, and Thomas,^[8] Tweedie et al.,^[7] and Larose and Dey,^[1] among others. It is evident, through these examples, that Bayesian meta-analysis is developing into an accepted approach in medical research.^[5,23,24]

As a more detailed example of the case that combines study-specific observed means and corresponding variances in a random-effects model, consider the fully Bayesian model proposed by DuMouchel^[21]

$$\begin{aligned} Y | \theta, \sigma^2 &\sim N(\theta, \sigma^2 C), & \sigma^{-2} &\sim \chi^2(df_\sigma)/(df_\sigma) \\ \theta | \mu, \tau^2 &\sim N(X\mu, \tau^2 V), & \tau^{-2} &\sim \chi^2(df_\tau)/(df_\tau) \\ \mu | \tau &\sim N(0, D \rightarrow \infty) \end{aligned}$$

where the $k \times k$ observed variance–covariance matrix C describes the within-study variability and the $k \times k$ prior variance–covariance matrix V is specified a priori or given a prior distribution such as a Wishart. For independent studies, C is taken as a diagonal matrix with individual variance estimates of Y_i on the diagonal. Uncertainty about matrices C and V is described by the parameters σ^2 and τ^2 , which are centered around unity (so that the expected values of the variances of Y and θ are C and V , respectively), given chi-squared priors with degrees of freedom df_σ and df_τ , so that larger degrees of freedom indicate greater confidence in these specified values. For example, the average number of exposed cases from each study could be used as a conservative estimate of df_σ , and the number of studies could indicate the magnitude of df_τ . The notation $D \rightarrow \infty$ indicates a very large prior variance on the overall mean, reflecting almost no prior information.

This model has been examined extensively by DuMouchel and coworkers.^[9,21,25,26] Other authors have compared it against alternatives and applied it to important public health problems such as the impact of passive smoking on health.^[7] Smith, Spiegelhalter, and Thomas^[8] also adopt this model, but their use of a more general Gamma distribution to represent variance parameters indicates that the variance representation is quite influential with respect to posterior distributions of the means and resultant inferences.

Prior Distributions

A feature that is exclusive to Bayesian modeling is the specification of prior beliefs as distributions. These specifications depend on the application. If the likelihood dominates the posterior, the posterior distribution is considered invariant over a wide range of priors. If not, priors must be developed with care and detailed in any publication.

An uninformative prior distribution, or reference prior, is designed to contain no information about a parameter (at least on one scale of interest) in that the produced posterior distribution equates to the likelihood. This approach is appealing if there is no prior information, beliefs, or expectations regarding parameters or studies, if it is necessary to present posterior distributions that reflect only objective sample information even in the presence of prior beliefs, or if it is very difficult to formulate an appropriate informative prior distribution. Jeffrey's prior is based on Fisher's information of the likelihood and is the most widely used method of obtaining potential reference priors.^[27] Improper uniform priors or proper but very diffuse priors are also often adopted as uninformative. It is important, though, to acknowledge the potential effects of these priors, including identifiability of the posterior, the weak contribution of the likelihood if the sample size is small or data are missing, the representation of the prior on other scales, and so on.^[14]

An informative prior incorporates information from various sources of evidence. These sources may include other studies or a meta-analysis of similar studies, pharmacological knowledge of a new medication, information regarding a treatment from previous data of similar medications, or the opinions of experts in their field. An informative prior is also important for obtaining a good representation of between-study heterogeneity if there are only a few studies in the meta-analysis. For example, skeptical priors formalize the belief that large treatment differences are unlikely, whereas an enthusiastic prior allows a small probability of no effect. Methodology and examples in which the prior distributions are based upon formally elicited subjective beliefs are relatively rare.^[28]

Semiparametric priors may also be considered, which may better accommodate asymmetric characteristics of uncertainty.^[29] Alternatively, instead of selecting a particular specification of a prior, a community of priors may be constructed that cover differing views. Such a community may include, for example, a reference prior, intended to add as little as possible to data, and a clinical prior, expressing reasonable opinions held by individuals.^[30]

Additional priors that may be considered include conjugate priors, which simplify calculations and produce easy to understand results as an analytic form of the mean and variance. Conjugate priors for μ and τ^2 are the normal and inverse gamma (IG) distributions, respectively. Non-informative priors may be approximated by a very flat normal distribution for μ and an IG distribution with near zero parameters for τ^2 .

An example of creating priors follows: Credibility of various evidence sources may be dubious and so the contribution of each study type to the overall population estimate is questioned. A reasonable assumption is that variability among RCTs is considerably less than that among non-RCTs. This information can be implemented by assuming each study type effect to have been drawn from differing population distributions that all share a common mean μ with different variances τ_i^2 . A higher τ_i^2 for a certain study type, for example, will relocate the estimated summary effect toward the other study types.

With respect to model (1) above, DuMouchel^[21] indicated that the specified prior distributions were selected on a convenience basis so that the posterior distribution of separate study effects is a mixture of multivariate Student-*t* distributions. A non-informative prior was used for the global population effect μ , because even with a small number of studies, the combined data are relatively informative about this parameter. Other potential prior distribution forms for the scale parameters include Pareto and log Cauchy distributions on σ^{-2} and $\tau^{-2[1]}$ or a uniform distribution on the standard deviation, σ .^[8]

COMPUTATION

In meta-analysis, there are often only a few parameters of particular interest. Inferences are based on the corresponding marginal posterior distributions for these parameters, after nuisance parameters are eliminated. For particular choices of the likelihood and priors, the marginal posterior distributions can be generated analytically by integrating the joint posterior density over remaining parameters.^[1] This comprises evaluating several high-dimensional integrals that do not permit analytical solutions for models with many parameters. Moreover, for non-standard distributions or where the normalizing constants are not available, analytic solutions are again not available.

In these circumstances, one alternative is to approximate the posterior. For example, DuMouchel^[21] suggested approximating the multivariate-*t* distributions arising from model (1) by multivariate normal distributions, which can then be described through the posterior mean and covariance matrices.^[1] As a second example, Morris and Normand^[31] proposed a Pearson approximation to the posterior distribution of the average of the overall variance term.

The posterior distribution can alternatively be obtained by simulation. The main computational method is Markov Chain Monte Carlo (MCMC).^[32] This method generates simulations from conditional posterior distributions, which, under mild assumptions, represent the joint posterior distribution.^[14] Common algorithms include Gibbs, Metropolis-Hastings, slice sampling, and perfect sampling.^[32]

MCMC methods are used to perform Bayesian inference in the computer software package BUGS (Bayesian inference Using the Gibbs sampling technique), which

is available at www.mrc-bsu.cam.ac.uk/bugs.^[33] Given a user-specified model in the form of likelihood and priors, BUGS constructs the necessary posterior conditional distributions, carries out MCMC sampling, provides statistical and graphical summaries of the posterior distributions, and reports some convergence diagnostics. Methods for assessing convergence of the MCMC simulation to the required distribution have been developed and discussed by many authors; see, for example, Spiegelhalter et al.,^[16] Robert and Casella,^[32] and Cowles and Carlin.^[34]

The WinBUGS manual gives worked examples of a number of meta-analyses relevant to the health and pharmacological profession. Congdon^[15] also uses WinBUGS to illustrate a wide range of Bayesian models and analysis, including meta-analysis.

Furthermore, DuMouchel^[35] developed an Splus function to implement a fully Bayesian meta-analysis which is publicly available. The empirical Bayes model can be also implemented in MLn,^[36] which requires the global mean to be normally distributed and uses bootstrapping to obtain standard errors for the model coefficients. Specialist routines are also available for particular approaches.

EXTENSIONS

Extending the Simple Hierarchical Model

The simple model described in Eq. (1) can be extended in various directions. For example, if studies are only exchangeable within subgroups, an additional hierarchy of group-specific distributions can be inserted between the study-specific and the global levels. For example, Wolpert and Mengersen^[37] describe a meta-analysis of log odds ratios, in which conditionally independent normal distributions are used to describe study-specific true log odds ratios that are centered at a country-group-specific level. The country-group means are then generated from a normal distribution that is centered at a global log odds ratio, whose distribution in turn is normally distributed and centered at zero, with a large variance. This indicates vague prior knowledge of the overall effect size. Informative priors derived from other study information are used for the other parameters.

Alternatively or in parallel, covariates can be added at any level to explain study or group differences. For example, fixed covariates are included in model (1) through the matrix X . If multiple outcomes are of interest, a multivariate analogue of the model can be easily developed;^[38] see also the separate article on Multivariate Meta-Analysis in this volume.

An empirical Bayesian model for meta-analysis is a more limited Bayesian approach that requires less information, because hyperparameters are specified rather than given full prior distributions and nuisance parameters are not integrated out as in a fully Bayesian model but instead

are eliminated by conditioning likelihoods.^[39] For example, an empirical Bayesian version of DuMouchel's^[21] model was proposed by Carlin^[19] in which C is taken to be a diagonal matrix with known study-specific variances, and the global variance τ^2 is replaced by its observed value. This approach is shown to have parallels with the popular frequentist random effects model described by Dersimonian and Laird.^[40]

Accounting for Bias

Publication bias, also referred to as the file drawer problem, arises when decisions about manuscripts that are accepted to publish are based on the statistical significance of results. Studies with statistically significant results are more likely to be published than are studies with non-significant or inconclusive results. Publication bias may also arise if theses of students are not published, or if studies are suppressed for a variety of reasons. Publication bias may be pervasive in scientific literature and can create potentially severe distortions in meta-analysis.^[17] Sutton, Abrams, and Jones,^[41] for example, reported an assessment of 48 meta-analyses in which about half demonstrated signs of potential publication bias. An investigation of publication bias by Tweedie et al.^[7] found that as much as 45% of the observed effect size of interest in this study could be because of publication bias. Tweedie et al.^[7] recommend that sensitivity of summary point estimate and confidence intervals to possible biases be acknowledged and accounted for when possible.

Several techniques have been presented to examine publication bias impact on results of a meta-analysis. These include graphical techniques to examine the presence of missing studies visually such as the common funnel plot^[6] and similar quantitative methods.^[42,43] Bayarri and Degroot^[44] use a Bayesian framework to examine the effect of different rules for selecting papers for publication, concluding that published significant results may support a hypothesis of no effect. Larose and Dey^[45] use weight functions to describe a variety of possible mechanism of publication bias, where the weight is in proportion to the probability of study results being published. The sensitivity of parameter estimates over a range of models can then be compared.

Various approaches have been proposed to estimate numbers of missing studies.^[18,44,45] Smith, Givens, and Tweedie^[18] adopt a Bayesian hierarchical model and data augmentation to examine the possibility of publication bias and MCMC to estimate the number of missing studies. The constraint of ascribing all publication bias to significance levels is removed by Givens, Smith, and Tweedie,^[17] who developed a multitier model that allow for other reasons for publication bias such as study quality or design, sample size, or population studied.

Adjustment for bias induced by study quality has also been provided in the context of Bayesian meta-analysis.

Studies will vary in quality because of different designs and different attempts to control for known biases, confounding, and misclassification. Wolpert and Mengersen^[37] describe a range of methods for combining data in a meta-analysis, including simple pooling, fixed and random effects, and exchangeable and partially exchangeable models. They then identify approaches for accounting for study quality, including threshold exclusion in which unfit studies are simply excluded from the analysis, likelihoods are weighted according to study quality, block mixtures are utilized in which studies are grouped according to quality and successively added to the analysis, and hierarchical models are used whereby separate estimation of treatment effects is performed for homogeneous studies. The authors propose an alternative approach that adjusts the likelihood directly for the specific quality issues and give a detailed illustration of the method by accounting for three types of misclassification in a hierarchical Bayesian model.

CONCLUSIONS

Bayesian approaches to meta-analysis are developing into accepted tools of analyses in medical literature. Bayesian approaches to meta-analysis offer more flexibility in terms of combining studies with differing aims, study characteristics, sampling frames, and reported information than the corresponding classical techniques. Different forms of uncertainty can be incorporated into the modeling process via the prior distributions, which can be based on various sources. The choice of prior distribution is dependent on the specific prior beliefs or expectations on the unknown quantities or parameters. Inferences are based on posterior distributions, which are commonly generated using MCMC methods. These methods can be implemented with the software package WinBUGS for which documentation is widely available. Furthermore, several methods have also been proposed for assessing and dealing with publication bias in the Bayesian framework, the choice of which is dependent on the particular source of bias.

Abstract

This entry aims to illustrate how a Bayesian approach to drug stability analysis naturally presents itself as a fundamentally legitimate way to provide a common ground in that it assumes some connection among batches, takes into account the batch-to-batch variation by defining appropriate prior distributions, and makes the use of prior knowledge on population parameters.

INTRODUCTION

Shelf-life or expiration dating period is one of the key components of biopharmaceutical products. The U.S. Food and Drug Administration (FDA) requires that the shelf-life, defined as the time interval during which the potency of a product is expected to remain within a pre-defined specification limit after manufacture, be indicated on the immediate container label. A formal stability study is usually conducted, as part of the new drug application (NDA) or investigational new drug (IND) to establish an appropriate shelf-life, or as post-marketing monitoring of product labeled shelf-life. Regulatory guidelines^[1,2] stipulate that at least three batches, preferably more, be tested to allow for some estimate of batch-to-batch variation and to provide the justification on which a single shelf-life for all batches is based.

Current practice for determination of shelf-life is to employ the linear fixed-effect model, or simply the analysis of covariance (ANCOVA) method to fit the stability data. The shelf-life is determined as the time point at which the lower one-sided confidence limit on the predicted mean intersects the pre-determined specification limit or minimum effective dose. To estimate the shelf-life for all batches, the ICH^[3] guideline suggests two-step statistical tests to determine whether the regression lines from different batches share a common slope and/or a common intercept given a common slope. Each of the tests uses a significance level of 0.25 to compensate for the expected low power due to the relatively small sample size. There have been some alternative offers in literature pertaining the poolability of batches, e.g., Ruberg and Stegeman,^[4] Ruberg and Hsu,^[5] Chen and Tsong,^[6] Tsong

et al.,^[7] and Liu et al.,^[8] where either a sequential hypothesis test or confidence interval approach is suggested. After the sequential tests, one ends up with one of the following decisions in terms of poolability: (i) individual slopes with individual intercepts, (ii) a common slope with individual intercepts, and (iii) a common slope with a common intercept. If decision (i) or (ii) is reached, one estimates individual shelf-lives by applying respective parameter estimates and pooled mean squared error, and chooses the shortest one as the shelf-life for all batches; if decision (iii) is achieved, one simply pools all the data together to obtain a common slope, a common intercept and a single shelf-life estimate for all batches.

Some authors have argued that the batches under study are sampled from all batches manufactured under similar circumstance, and thus it would be more appropriate to consider the batches as correlated and the batch effects as random. Chow and Shao^[9,10] are among the first who studied batch-to-batch variation in drug stability study and proposed a random-effect model for shelf-life estimation by assuming random slopes and random intercepts from batches. Some recent developments on random-effect models for drug stability studies include Shao and Chow^[11] and Chen et al.^[12] However, as pointed out in Chen et al.,^[13] the random-effect models may be more appropriate in some situation such as post-marketing stability studies where a large number of batches are tested; there are at least two drawbacks to this approach. First, a small number of batches tested in the IND and NDA stability studies may result in unreliable estimates of random-batch effect. Second, as a frequentist method, it does not utilize any prior information that might have been available on parameters. Following the ideas in Chen et al.,^[13] this entry aims to

illustrate how a Bayesian approach to drug stability analysis naturally presents itself as a fundamentally legitimate way to provide a common ground in that it assumes some connection among batches, takes into account the batch-to-batch variation by defining appropriate prior distributions, and makes the use of prior knowledge on population parameters. With available software packages such as WinBUGS and R, one can easily implement the computational algorithm of Bayesian methods in determining the poolability of batches and posterior shelf-life estimation of drug products.

PRELIMINARIES AND NOTATIONS

Suppose that k batches are taken in a stability study. Let y_{ij} be the observed value of the j th assay result (percent of label claim) from the i th batch, then the following model can be assumed:

$$y_{ij} = \alpha_i + \beta_i(x_{ij} - \bar{x}_i) + \varepsilon_{ij}, \quad i = 1, \dots, k, j = 1, \dots, n_i, \quad (1)$$

where α_i and β_i are, respectively, the unknown individual regression intercept and slope for batch i , x_{ij} is the known time point determined at the design stage, $\bar{x}_i = \sum_{j=1}^{n_i} x_{ij}/n_i$, and ε_{ij} are iid $N(0, \sigma^2)$ corresponding to the random error of y_{ij} . Here the i th regression line is shifted towards $\bar{x}_i$; the “centering” of x_{ij} values about their mean leads to algebraic simplifications and better computational and statistical properties of the estimates.^[14] Eq. 1 is called the linear fixed-effect model if α_i and β_i are considered as fixed effects.

Equality of individual slopes in Eq. 1 can be formally checked by performing the null hypothesis test $H_\beta: \beta_1 = \dots = \beta_k$ against $\bar{H}_\beta$: at least one β_i is not equal to the others. If H_β is rejected, then the test stops and Eq. 1 with individual slopes and individual intercepts is assumed; if H_β is not rejected, then the assumption of a common intercept for the k batches is examined by testing the null hypothesis $H_\alpha: \alpha_1 = \dots = \alpha_k$ against $\bar{H}_\alpha$: at least one α_i is not equal to the rest, given a common slope β . If H_α is rejected, then Eq. 1 with β_i being replaced by a common slope β is taken; if H_α is not rejected, then Eq. 1 with α_i being replaced by a common intercept α and β_i by β is assumed. These two tests can easily be accomplished by ANCOVA. Given the decision on whether or not the batches are poolable, one calculates the corresponding intercept(s), slope(s) as well as the (pooled) mean squared error, and then estimate the shelf-life that applies to all batches according to the so-called minimum approach.^[3] That is, if the batches are not completely poolable (decisions (a) and (b)), the shelf-lives for individual batches are calculated and the shortest shelf life is chosen as the shelf-life for all batches; on the other hand, if the batches are completely poolable (decision (c)), then a single shelf life is calculated as the

shelf life for all batches. For technical details of current practice on the poolability tests and shelf-life estimation of frequentist methods, either fixed effect or random-effect model, the reader is referred to Chow and Liu^[15] and Chow.^[16]

A BAYESIAN HIERARCHICAL APPROACH

A Bayesian approach relies on the specification of hierarchical structure of Eq. 1 being the data model. Given the data and a set of prior distributions, one proceeds with poolability tests using Bayes factors (or other Bayes means for hypothesis test) and then shelf-life estimation using posterior distributions of relevant parameters.

The Hierarchical Model

This subsection describes how the prior distributions can easily be defined and what points should be taken into account in specifying the priors. Although there are many different ways to specify the hierarchical models, what we offer below represents our prior believes on the process parameters. In all cases, the prior specification should totally be up to one's prior knowledge on drug development steps, such as manufacturing release, drug potency change over time, and other parameters in the study.

It is fairly reasonable to assume that, conditional on some hyper-parameter λ , $\alpha = \{\alpha_1, \dots, \alpha_k\}$, $\beta = \{\beta_1, \dots, \beta_k\}$ and σ^2 are mutually independent. The independence between α and β is practically valid, especially under Eq. 1 in which the maximum likelihood estimates of α_i and β_i are uncorrelated.

Given the above assumption, the prescription for the prior densities of α_i and β_i follows the hierarchical structure as given in Berger,^[17] (section 4.6), and hence consists of two stages: a distribution for α_i and β_i , $i = 1, \dots, k$, given $\lambda = (\mu, \xi, \sigma^2)$ and a distribution for $\lambda = (\mu, \xi, \sigma^2)$, where $\mu = (\mu_\alpha, \mu_\beta)$ and $\xi = (\xi_\alpha, \xi_\beta)$. Specifically, for the first stage prior $\pi_1(\alpha_i, \beta_i | \lambda)$, we take

$$\pi_1(\alpha_i, \beta_i | \lambda) = \pi_{11}(\alpha_i | \mu_\alpha, \xi_\alpha, \sigma^2) \pi_{12}(\beta_i | \mu_\beta, \xi_\beta, \sigma^2), \quad i = 1, \dots, k, \quad (2)$$

with

$$\pi_{11}(\alpha_i | \mu_\alpha, \xi_\alpha, \sigma^2) = N(\mu_\alpha, \xi_\alpha \sigma^2)$$

and

$$\pi_{12}(\beta_i | \mu_\beta, \xi_\beta, \sigma^2) = N(\mu_\beta, \xi_\beta \sigma^2).$$

Let the second stage prior be

$$\pi_2(\mu, \xi, \sigma^2) = \pi_{211}(\mu_\alpha) \pi_{212}(\mu_\beta) \pi_{221}(\xi_\alpha) \pi_{222}(\xi_\beta) \pi_{223}(\sigma^2), \quad (3)$$

with

$$\begin{aligned}\pi_{211}(\mu_\alpha) &= 1, \\ \pi_{212}(\mu_\beta) &= U(\theta, 0), \\ \pi_{221}(\xi_\alpha) &= \pi_\alpha I(\xi_\alpha = 0) + (1 - \pi_\alpha) \pi_{221}^*(\xi_\alpha) I(\xi_\alpha > 0), \\ \pi_{222}(\xi_\beta) &= \pi_\beta I(\xi_\beta = 0) + (1 - \pi_\beta) \pi_{222}^*(\xi_\beta) I(\xi_\beta > 0), \\ \pi_{223}(\sigma^2) &= \sigma^{-2}\end{aligned}$$

where I is an indicator function of respective parameters, π_α and π_β are some subjectively chosen constants, and $\pi_{221}^*(\xi_\alpha)$ and $\pi_{222}^*(\xi_\beta)$ are arbitrary. Hence, the hyperparameter μ_α is given a non-informative prior and μ_β a uniform distribution in $(\theta, 0)$, a class of constrained non-informative priors. The constraint $\theta < 0$ forces the degradation rate to be negative *a priori*, indicating a prior believe on non-increasing trend of potency over time. In addition, σ^2 is also given a non-informative prior which is a limit of proper conditionally-conjugate inverse-gamma $IG(a, b)$ density with $a, b \rightarrow 0$, a commonly used class of priors for normal variance.

The prior parameters π_α and π_β can be interpreted as the prior probabilities of the null hypotheses $H_\alpha : \alpha_1 = \dots = \alpha_k$ and $H_\beta : \beta_1 = \dots = \beta_k$ being true, respectively, because π_α is the probability for $\sigma_\alpha^2 = \xi_\alpha \sigma^2 = 0$ (hence H_α holds) and π_β for $\sigma_\beta^2 = \xi_\beta \sigma^2 = 0$ (hence H_β holds). The most common use of these special forms of mixture prior distributions on σ_α^2 and σ_β^2 is to test the equality of parameters, such as normal means, from multiple populations. A natural choice for π_α and π_β would conventionally be non-informative $\pi_\alpha = \pi_\beta = 1/2$ unless otherwise some subjective prior belief on H_α or H_β is available.

Although $\pi_{221}^*(\xi_\alpha)$ and $\pi_{222}^*(\xi_\beta)$ could also be non-informative, they are usually chosen to be informative, especially in testing situation. The default prior $\pi_{221}^*(\xi_\alpha)$ that we adopt in this testing problem is an inverse gamma distribution $IG(1/2, 1/2)$. The advantage for this prior is that the resulting conditional distribution $\pi(\alpha | \sigma^2)$ of α , when $k = 1$, is Cauchy (μ_α, σ^2) , an analysis recommended by.^[18] With a similar argument, we take $\pi_{222}^*(\xi_\beta) = IG(1/2, 1/2)$.

Testing for Poolability of Batches

Testing the equality of slopes and equality of intercepts given a common slope can be approached in different ways in the Bayesian context, such as F test^[19] and model selection using pairwise Bayes factors between models.^[20] However, the specification of mixture priors for the variance parameters ξ_α and ξ_β allows us to pursue the poolability tests through Bayes factors for prior variances being equal to 0 versus that they are greater than 0.

Testing Equality of Slopes With Individual Intercepts

Suppose that given individual intercepts, we want to test $H_\beta : \beta_1 = \dots = \beta_k$ against $\bar{H}_\beta : \text{not all the } \beta_i \text{'s are equal}$. This

is a typical analysis of variance problem and is equivalent to testing the null hypothesis $H_{\xi_\beta} : \xi_\beta = 0$ against $\bar{H}_{\xi_\beta} : \xi_\beta \neq 0$. Following Berger^[17] (pp. 149–150) and Berger and Deely,^[21] we first define

$$L(\xi_\beta) = \int f(y | \alpha, \beta, \sigma^2) \pi_1(\alpha, \beta | \mu, \xi, \sigma^2) \times \pi_2(\mu, \xi, \sigma^2) d\alpha d\beta d\mu d\sigma^2 d\xi_\alpha \quad (4)$$

as the likelihood of ξ_β and

$$K_\beta(y) = \int L(\xi_\beta) \pi_{222}^*(\xi_\beta) d\xi_\beta \quad (5)$$

as the marginal p.d.f. of y with respect to $\pi_{222}^*(\xi_\beta)$. Then, the Bayes factor (B) for testing H_{ξ_β} (or H_β) against $\bar{H}_{\xi_\beta}$ (or $\bar{H}_\beta$) is given by

$$B_\beta = \frac{L(\xi_\beta = 0)}{K_\beta(y)} \quad (6)$$

The resulting Bayes factor B_β is compared with a constant c . If $B_\beta < c$, then H_β is rejected; otherwise H_β is retained. Although different authors^[22–24] have suggested using different constants for rejecting the null hypothesis, we will, adopt the principle of Berger et al.^[23] and use 1 for the constant c . This makes sense because a Bayes factor less than 1 would simply imply that the null model is less likely to be true as compared with the alternative model.

Testing Equality of Intercepts With a Common Slope

If H_{ξ_β} is not rejected, then the degradation rates for all batches are considered to be equal. Given this hypothesis being true, we now want to know whether the initial potencies at time 0 are equal for all batches by testing the null hypothesis $H_\alpha : \alpha_1 = \dots = \alpha_k$ against $\bar{H}_\alpha : \text{not all the } \alpha_i \text{'s are equal}$. Similar to testing H_β , this can be accomplished by testing the null hypothesis $H_{\xi_\alpha} : \xi_\alpha = 0$ against $\bar{H}_{\xi_\alpha} : \xi_\alpha \neq 0$, conditional on $\xi_\beta = 0$. The Bayes factor for testing H_{ξ_α} against $\bar{H}_{\xi_\alpha}$ is given by

$$B_\alpha = \frac{L(\xi_\beta = 0, \xi_\alpha = 0)}{K_\alpha(y)}, \quad (7)$$

where $L(\xi_\beta = 0, \xi_\alpha = 0)$ is the likelihood of $\xi = (\xi_\alpha, \xi_\beta)$ evaluated at $\xi_\alpha = 0$ and $\xi_\beta = 0$, and

$$K_\alpha(y) = \int L(\xi_\alpha, \xi_\beta = 0) \pi_{221}^*(\xi_\alpha) d\xi_\alpha$$

is the marginal p.d.f. of y with respect to $\pi_{221}^*(\xi_\alpha)$ conditional on $\xi_\beta = 0$. Again the decision on rejection or acceptance of H_{ξ_α} is made by comparing the resulting Bayes factor B_α with c ; if $B_\alpha < c$ then H_{ξ_α} is rejected; otherwise H_{ξ_α} is accepted.

Shelf-Life Estimation

Instead of using confidence limits as in frequentist methods, a Bayesian employs credible limits on the mean predicted values that are based on the posterior distributions of regression parameters to estimate drug shelf-life, denoted by y^B . In this subsection we present some necessary formulas for calculating y^B for various situations corresponding to the decisions of poolability of batches resulted from the hypothesis testing, as discussed in the previous subsection.

Suppose that the Bayesian test of $H_{\xi\beta}$ rejects the null hypothesis of equality of slopes among batches, then decision (a) is reached and shelf-lives are calculated separately for individual batches using the credible limits on individual regression lines. It is straightforward to see that conditional on (y, μ, ξ, σ^2) , α_i and $\beta_i, i = 1, \dots, k$, are independently and normally distributed with $\alpha_i \sim N(\hat{\alpha}_i^B, \sigma^2 v_{\alpha i})$ and $\beta_i \sim N(\hat{\beta}_i^B, \sigma^2 v_{\beta i})$, where $\hat{\alpha}_i^B$ and $\hat{\beta}_i^B$ are respective posterior estimates of α_i and β_i , and $v_{\alpha i}$ and $v_{\beta i}$ are posterior estimates of their variance factors. For any given x' , the $100(1-\gamma)\%$ one-sided lower credible limit for the predicted mean potency $p_i^B = \alpha_i^B + \beta_i^B(x' - \bar{x}_i)$ is given by

$$\ell_i^B(x') = \hat{p}_i^B - z_{1-\gamma} \sigma \sqrt{v_{\alpha i} + v_{\beta i}(x' - \bar{x}_i)^2}, \quad i = 1, \dots, k, \quad (8)$$

where $\hat{p}_i^B = \hat{\alpha}_i^B + \hat{\beta}_i^B(x' - \bar{x}_i)$, $z_{1-\gamma}$ is the $100(1-\gamma)\%$ th percentile of the standard normal distribution. Consequently, the shelf-life for all batches is given by

$$\psi^B = \inf\{x_i \geq 0 : l_i^B(x') \leq \eta\}, \quad (9)$$

the smallest x' that satisfies $l_i^B(x') = \eta$

Similarly, if the Bayesian test of $H_{\xi\beta}$ fails to reject the null hypothesis of equality of slopes and the test of $H_{\xi\alpha}$ concludes inequality of intercepts, then decision (b) is made and the credible limits for individual batches are obtained using the posterior distributions of the common slope β^B and individual intercepts α_i^B . Some algebra can show that conditional on (y, μ, ξ, σ^2) , α_i and β are independent and normally distributed with $\alpha_i \sim N(\hat{\alpha}_i^B, \sigma^2 v_{\alpha i}), i = 1, K, k$, and $\beta \sim N(\hat{\beta}^B, \sigma^2 v_{\beta})$, where $\hat{\beta}^B$ is the posterior estimate of the common slope β and v_{β} the posterior estimate of its variance factor. Hence, the $100(1-\gamma)\%$ one-sided lower

credible limit for the posterior mean predicted potency $p_{\alpha i}^B = \alpha_i + \beta(x' - \bar{x}_i)$ is obtained as

$$l_i^B(x') = \hat{p}_{\alpha i}^B - z_{1-\gamma} \sigma \sqrt{v_{\alpha i} + v_{\beta i}(x' - \bar{x}_i)^2}, \quad i = 1, K, k, \quad (10)$$

where $\hat{p}_i^B = \hat{\alpha}_i^B + \hat{\beta}^B(x' - \bar{x}_i)$, and $\hat{\alpha}_i^B$ and $v_{\alpha i}$ are as defined in (8). The shelf-life for all batches is determined using the minimum approach as defined in (9).

Finally, if both tests of $H_{\xi\beta}$ and $H_{\xi\alpha}$ fail to reject the respective null hypotheses of equality of slopes and equality of intercepts, then decision (c) is reached and the data of all batches are pooled to obtain the posterior estimates of the common slope β and the common intercept α . Conditional on (y, μ, ξ, σ^2) , α and β are independent and $\alpha \sim N(\hat{\alpha}^B, \sigma^2 v_{\alpha})$, where $\hat{\alpha}^B$ is the posterior estimate of the common intercept α and v_{α} the posterior estimate of its variance factor. The $100(1-\gamma)\%$ lower credible limit for the posterior mean predicted potency $p^B = \alpha^B + \beta^B(x' - \bar{x})$ is

$$l^B(x') = \hat{p}^B - z_{1-\gamma} \sigma \sqrt{v_{\alpha} + v_{\beta}(x' - \bar{x})^2}, \quad (11)$$

where $\hat{p}^B = \hat{\alpha}^B + \hat{\beta}^B(x' - \bar{x})$, and $\hat{\beta}^B$ and v_{β} are as given in (10). It should be pointed out that for simplicity we have assumed a known value of σ^2 and used normal approximation to obtain the credible limits. In reality, σ^2 must be estimated and applied to the above estimation, and the normal percentile z score should be replaced by the percentile of the t distribution with appropriate degrees of freedom.^[19] This may be more important for studies with a small sample size such as NDA studies.

Obviously there are no closed forms of the Bayes factors and the unconditional posterior distributions of parameters of interest. The Bayes factors and shelf-lives have to be therefore estimated through Markov chain Monte Carlo (MCMC) methods. Consequently, all computations can be carried out in R and WinBUGS. Readers who are interested in trying other software packages are referred to WinBUGS. Readers who are interested in trying other software packages are referred to Chen et al.^[13] for the complete conditional posterior distributions of all parameters involved in the MCMC under various combinations of the null hypotheses for the hierarchical setting discussed above.

Table 1 NDA Stability Study: Potency Assay Results (Percent of Claim)^[9]

Batch	Time (month)						
	0	3	6	9	12	18	24
1	101	97	96	95	95	94	92
2	102	100	99	100	102	102	100
3	100	104	96	98	97	96	99

AN EXAMPLE

We illustrate the proposed Bayesian approach through an example of an NDA stability study. The data set, taken from Chow and Shao,^[9] consists of three batches with each tested at time points 0, 3, 6, 9, 12, 18, 24 and 36 months (Table 1). We first applied the ANCOVA and the likelihood ratio test, as discussed in Chen et al.,^[13] to test the equality of slopes and obtained the p -values being 0.0561 and 0.0380, respectively, which exceed the ICH guideline's suggested cutoff p -value of 0.25. Hence, we employed the respective linear fixed-effect model with individual slopes and individual intercepts and the linear random-effect model with both coefficients being random to estimate the shelf-lives for all future batches. Such estimated shelf-lives for $\eta = 90$ are 28.96 months by the linear fixed-effect model and 25.77 months by the random-effect model.

We then applied the proposed Bayesian hierarchical approach to the example data set with the same hierarchical prior structure as prescribed in section "A Bayesian Hierarchical Approach" and $\theta = -0.3$, we obtained a Bayes factor $B_\beta = 0.0160$ for testing the null hypothesis of equal slopes which leads to the rejection of the null hypothesis $H_{\beta\beta}$. Accordingly, the shelf-lives for the three batches are calculated separately based on the posterior densities of (α_i, β_i) and the minimum of such estimated shelf-lives is 29.53 months.

CONCLUDING REMARKS

Bayesian hierarchical modeling approach has abroad application in a variety of fields; it might be even more appropriate in the biopharmaceutical industry where heavy regulations and frequent testing take place throughout product development. The rationale behind this is that some prior information can easily be derived from regulation parameters and many specifications on product release. For instance, a drug product can only be released to the market after manufacture if its release tests satisfy a set of pre-prescribed specification limits, especially the potency limits that may serve as the extreme points for the prior on $\mu\alpha$. Also, the potency specification limits may be used to derive the prior distribution of variance parameter for the regression intercept. The prior distribution for degradation parameter may be obtained from a collection of pilot study, manufacturing process, product formulation as well as storage conditions. In case of no other prior information available, non-informative priors can always be used.

In this research we used threshold value $c = 1$ for the Bayes factor. It would be interesting to see how the choice of this threshold value affect the power, conditional power, and estimated shelf-lives in particular, under various designs. Although we illustrated the

hierarchical model in the balanced design, it is applicable to most of the stability designs including bracketing design, matrix design, and some recently proposed stability designs.^[25] A more complex design with covariates such as package type and dosage strength can also be accommodated by including more parameters and their priors, in which case an attention should be given to the balance of the number of data points and the number of parameters including hyperparameters to ensure their identifiability.

Abstract

This entry presents definition for the prior effective sample size (ESS) of a parametric prior distribution in a Bayesian model, and proposes methods for computing the prior ESS for a wide variety of Bayesian parametric models, and also discusses the implementation of this method in specific Bayesian biomedical data analysis and clinical trial design settings.

Keywords: Bayesian analysis; Bayesian clinical trial design; Parametric prior distribution; Prior effective sample size.

INTRODUCTION

Understanding the strength of a prior distribution relative to the likelihood is a fundamental issue when applying Bayesian methods. The processes of formulating a putatively non-informative prior or eliciting a prior from an area expert typically require one to make many arbitrary choices, including choosing particular distributional forms and specifying numerical hyperparameter values. In practice, these choices are often dictated by technical convenience. A common criticism of Bayesian analysis is that an inappropriately informative prior may unduly influence posterior inferences and decisions. These issues may be addressed directly by quantifying the prior information in terms of a number of hypothetical patients, that is, a prior effective sample size (ESS). Such a summary allows one to judge the relative contributions of the prior and the data to the final conclusions. A useful property of prior ESS is that it is readily interpretable by any scientifically literate reviewer without requiring expert mathematical training. This is important, for example, for consumers of clinical trial results.

For some distributions, computing the prior ESS is straightforward. An example is the beta prior, $Be(a, b)$ commonly used for the success probability of a binomial sampling model, which is well known to have $ESS = a + b$. However, there is no obvious answer for many widely used models, including such basic models as a normal linear regression model with conjugate priors. We present a definition for the prior ESS of a parametric prior distribution in a Bayesian model, and propose methods for computing the prior ESS for a wide variety of Bayesian parametric models.^[1] In addition, we discuss the implementation of this method in specific Bayesian biomedical data analysis and clinical trial design settings.

PRIOR EFFECTIVE SAMPLE SIZE

The intuitive motivation for our method is to mimic the rationale for why the ESS of a $beta(a, b)$ equals $a + b$. If a binomial random variable Y from a sample of size n has success probability θ following a $beta(a, b)$ prior, then θ follows a $beta(a + Y, b + n - Y)$ posterior. In terms of ESS, given a sample of size n , the prior sum $a + b$ becomes the posterior sum $a + b + n$. Thus, saying that a given $beta(a, b)$ prior has ESS $m = a + b$ requires the implicit reasoning that the $beta(a, b)$ may be identified with a $beta(c + Y, d + m - Y)$ posterior arising from a previous $beta(c, d)$ prior having a very small amount of information. A simple way to formalize this is to set $c + d = \varepsilon$ for an arbitrarily small value $\varepsilon > 0$ and solve for $m = a + b - (c + d) = a + b - \varepsilon$.

As a general Bayesian framework, let $f(Y | \theta)$ denote the sampling model for a random vector Y with parameter vector $\theta = (\theta_1, \dots, \theta_d)$. That is, f is a parametric probability distribution function (pdf) or probability mass function (pmf). Denote $Y_m = (Y_1, \dots, Y_m)$, with $Y_i \sim f(Y_i | \theta)$ an i.i.d. sample. The likelihood is $f_m(Y_m | \theta) = \prod_{i=1}^m f(Y_i | \theta)$. Let $p(\theta | \tilde{\theta})$ be the prior on θ with hyperparameters $\tilde{\theta}$. An ε -information prior, $q_0(\theta | \tilde{\theta}_0)$, is defined by requiring matching means, $E_{q_0}(\theta) = E_p(\theta)$, and correlations, $Corr_{q_0}(\theta_j, \theta_{j'}) = Corr_p(\theta_j, \theta_{j'})$, $j \neq j'$, while inflating the variances of the elements of θ , with the requirement that $Var_{q_0}(\theta_j)$ must exist for each $j = 1, \dots, d$. The idea is that $q_0(\theta | \tilde{\theta}_0)$ is a version of $p(\theta | \tilde{\theta})$ that has a very small amount of information. For example, when $p(\theta | \tilde{\theta})$ is a beta distribution, $Be(\tilde{\alpha}, \tilde{\beta})$, $q_0(\theta | \tilde{\theta}_0)$ is specified as $Be(\tilde{\alpha}/c, \tilde{\beta}/c)$ using an arbitrarily large value $c > 0$, so that the $ESS = (\tilde{\alpha} + \tilde{\beta})/c$ of q_0 is very small while

the mean is still $\tilde{\alpha}/(\tilde{\alpha} + \tilde{\beta})$. Given a sample $\mathbf{Y}_m$ and an ε -information prior $q_0(\boldsymbol{\theta}|\tilde{\boldsymbol{\theta}}_0)$, we denote the posterior by $q_m(\boldsymbol{\theta}|\tilde{\boldsymbol{\theta}}_0, \mathbf{Y}_m) \propto q_0(\boldsymbol{\theta}|\tilde{\boldsymbol{\theta}}_0) f_m(\mathbf{Y}_m|\boldsymbol{\theta})$.

To define the prior-to-posterior distance between $p(\boldsymbol{\theta}|\tilde{\boldsymbol{\theta}})$ and $q_m(\boldsymbol{\theta}|\tilde{\boldsymbol{\theta}}_0, \mathbf{Y}_m)$, the basic idea is to find the sample size, m , that would be implied by normal approximations of the prior $p(\boldsymbol{\theta})$ and the posterior $q_m(\boldsymbol{\theta}|\tilde{\boldsymbol{\theta}}_0, \mathbf{Y}_m)$. The second derivatives of the log densities are used to define the distance in terms of the trace of the information matrix (minus 2nd derivative of the log density) of the prior $p(\boldsymbol{\theta}|\tilde{\boldsymbol{\theta}})$ and the expected information matrix of the posterior $q_m(\boldsymbol{\theta}|\tilde{\boldsymbol{\theta}}_0, \mathbf{Y}_m)$, where the expectation is with respect to the marginal $f_m(\mathbf{Y}_m)$. The ESS of $p(\boldsymbol{\theta}|\tilde{\boldsymbol{\theta}})$ with respect to the sampling distribution $f(\mathbf{Y}|\boldsymbol{\theta})$ is defined to be the interpolated value of m minimizing the distance. If interest is focused on a subvector $\boldsymbol{\theta}_r$ of $\boldsymbol{\theta}$, the ESS can be determined similarly in terms of the marginal prior $p(\boldsymbol{\theta}_r|\tilde{\boldsymbol{\theta}})$. The reader is referred to Morita, Thall and Müller (MTM)^[1] for details of these definitions.

COMPUTATIONAL METHODS

We briefly summarize computational methods for obtaining ESS, details of which are provided in MTM.^[1] First, the following algorithm is used for computing prior ESS(s). Let M be a positive integer chosen so that it is reasonable to assume that $m \leq M$.

Step A1. Specify $q_0(\boldsymbol{\theta}|\tilde{\boldsymbol{\theta}}_0)$.

Step A2. For each $m = 0, \dots, M$, compute the prior-to-posterior distance

Step A3. The ESS is the interpolated value of m minimizing the distance.

Steps A2 and A3 may be repeated to compute the ESSs for subvectors of $\boldsymbol{\theta}$, when subvector-specific ESS values as well as the ESS for the whole vector $\boldsymbol{\theta}$ may be of interests. When the expected information matrix of the posterior $q_m(\boldsymbol{\theta}|\tilde{\boldsymbol{\theta}}_0, \mathbf{Y}_m)$ cannot be computed analytically, the simulation-based numerical approximation is used.

The following algorithm may be used to calibrate the hyperparameters of prior distributions of subvectors of $\boldsymbol{\theta}$ using ESSs. Assume that $\tilde{\boldsymbol{\theta}} = (\tilde{\boldsymbol{\theta}}_1, \tilde{\boldsymbol{\theta}}_2)$ and $\dim(\tilde{\boldsymbol{\theta}}) = 2$.

Step B1. Specify a prior ESS value.

Step B2. Fix $\tilde{\boldsymbol{\theta}}_1$.

Step B3. Find $\tilde{\boldsymbol{\theta}}_2$ to achieve the specified ESS.

Step B4. Repeat Steps B2 and B3 for a range of $\tilde{\boldsymbol{\theta}}_1$. The values of $(\tilde{\boldsymbol{\theta}}_1, \tilde{\boldsymbol{\theta}}_2)$ define a contour of equal ESS value.

Step 5. Repeat Steps B1 to B4 for a set of ESSs values.

When $p = \dim(\tilde{\boldsymbol{\theta}}) \geq 3$, we suggest two strategies to reduce the dimension of the plot to two coordinates of

$\tilde{\boldsymbol{\theta}}$. Introduce constraints, such as $\tilde{\boldsymbol{\theta}}_2 = \tilde{\boldsymbol{\theta}}_3$. Alternatively fix $(\tilde{\boldsymbol{\theta}}_3, \dots, \tilde{\boldsymbol{\theta}}_p)$ at some value and carry out steps B2 through B5 for $(\tilde{\boldsymbol{\theta}}_1, \tilde{\boldsymbol{\theta}}_2)$.

APPLICATIONS TO DATA ANALYSIS AND STUDY DESIGN

Cross-tabulated Counts from Small Samples

Carlin^[2] analyzed small-sample contingency table data from an experiment carried out to examine the effects of mechanical ventilator devices on lung damage in rabbits. In the experiment, the lungs of newborn rabbits were altered to simulate lung defects seen in human infants with underdeveloped lungs due to premature birth. The aim was to learn about the joint effects of different frequency and amplitude settings of the ventilators on lung damage. Six groups of six to eight animals each were compared using a factorial design with three frequency values crossed with two amplitudes. For amplitude indexed by $g = 1, 2$ for 20 and 60 respectively and frequency indexed by $h = 1, 2, 3$ for 5, 10, and 15 Hz, let $Y_{g,h}$ denote the number of animals with lung damage out of $n_{g,h}$ studied and let $\pi_{g,h}$ denote the probability of lung damage. The data are shown in Table 1, where each cell reports the empirical frequency $Y_{g,h}/n_{g,h}$. Carlin^[2] assumed the following logistic regression model

$$\pi_{g,h}(\boldsymbol{\theta}) = \text{logit}^{-1}(\mu + \alpha_g + \beta_h + \gamma_h I_{(g=2)}),$$

where $I_{(g=2)}$ indicates $(g = 2)$. The parameters α_g and β_h are main effects for amplitude and frequency while γ_h is the interaction effect at frequency h and amplitude $g = 1$. Hence, the model parameter is $\boldsymbol{\theta} = (\mu, \alpha_1, \alpha_2, \beta_1, \beta_2, \beta_3, \gamma_1, \gamma_2, \gamma_3)$.

Assuming a binomial model, $Y_{g,h} | \boldsymbol{\theta} \sim \text{Bin}(n_{g,h}, \pi_{g,h}(\boldsymbol{\theta}))$, the likelihood is

$$f(\mathbf{Y}_m | \boldsymbol{\theta}) \propto \prod_{g=1}^2 \prod_{h=1}^3 \pi_{g,h}(\boldsymbol{\theta})^{Y_{g,h}} \{1 - \pi_{g,h}(\boldsymbol{\theta})\}^{n_{g,h} - Y_{g,h}}$$

Carlin^[2] assumed independent normal priors for $\mu, \{\alpha_g\}, \{\beta_h\}$, and $\{\gamma_h\}$,

Table 1 The Effects of Mechanical Ventilator Devices on Lung Damage in Rabbits (Carlin, 2002)^[2]; Each Cell Contains the Number of animals with Lung Damage Over the Number Studied at the (Amplitude, Frequency) Combination

Amplitude	Frequency (Hz)		
	5	10	15
20	1/6	0/6	0/6
60	4/6	0/6	4/8

$$\mu \sim N(0, 1000^2), \alpha_g \sim N(0, \tilde{\sigma}_\alpha^2), \beta_h \sim N(0, \tilde{\sigma}_\beta^2), \gamma_h \sim N(0, \tilde{\sigma}_\gamma^2). \quad (1)$$

We use prior ESS to investigate sensitivity of inferences to hyperparameter values by considering seven alternative choices that cover a range of reasonably non-informative settings. The seven hyperparameter choices (N1 to N7) are shown in Table 2.

For each $\tilde{\theta}$, we compute an overall ESS for $p(\theta | \tilde{\theta})$, and also $ESS_\mu, ESS_\alpha, ESS_\beta$, and ESS_γ , for the marginal priors on the subvectors $\mu, \alpha = (\alpha_1, \alpha_2), \beta = (\beta_1, \beta_2, \beta_3)$, and $\gamma = (\gamma_1, \gamma_2, \gamma_3)$ of θ . For convenience, below we will refer to the elements of θ as $\theta_1, \dots, \theta_9$. Let $D_{p,j}(\theta)$ and $D_{q,j}(m, \theta, Y_m)$ denote the j th diagonal elements of the information matrices of the prior $p(\theta | \tilde{\theta})$ and the posterior $q_m(\theta | \tilde{\theta}_0, Y_m)$, respectively. We specify an ε -information prior by inflating the variances in (1) by multiplying the variance hyperparameters by $c = 10,000$. It is straightforward to derive analytically that $D_{p,j}(\theta) = \tilde{\sigma}_\theta^{-2}$ and $D_{q,j}(m, \theta, Y_m) = \sum_{g,h} m_{g,h} \pi_{g,h} (1 - \pi_{g,h})$, for each $j = 1, \dots, 9$. Each $D_{q,j}$ depends on the numbers of animals in the cells but not on Y_m , which greatly simplifies averaging $D_{q,j}(m, \theta, Y_m)$ over the future data Y . The ESS values are summarized in Table 2.

The prior N7 with $\tilde{\sigma}_\alpha = \tilde{\sigma}_\beta = \tilde{\sigma}_\gamma = 0.5$ has $ESS = 36.6$, so that it has impact roughly equal to that of the data (sample size $n = 36$) on any posterior inference. Thus, based on its ESS, the prior N7 may be criticized as being overly informative. The priors N4 and N7 both assume very high prior information for the interaction effects. Both priors have $ESS_\gamma = 96.1$. Because the prior means of the interactions are 0, these priors have the effect of shrinking the posterior estimates of the interactions excessively toward 0. This illustrates the importance of evaluating not only the overall ESS, but also the ESS values of subvectors of θ that have particular interpretations in the model. Such ESS computations help readers to interpret the reported posterior results, such as the estimates between the frequency groups displayed in Carlin (Fig. 1).^[2] In this example, since the sample size is 38, the ESS_γ computation shows that the value $\tilde{\sigma}_\gamma = 0.5$ is far too small.

Table 2 Summary of Priors (Standard Error Parameters) and Computed ESSs

	$\tilde{\sigma}_\alpha$	$\tilde{\sigma}_\beta$	$\tilde{\sigma}_\gamma$	ESS	ESS_μ	ESS_α	ESS_β	ESS_γ
N1	2.0	2.0	2.0	2.3	<0.001	2.0	3.0	6.0
N2	1.5	1.5	1.5	4.1	<0.001	3.6	5.3	10.6
N3	1.5	1.5	1.0	6.0	<0.001	3.6	5.3	23.9
N4	1.5	1.5	0.5	16.3	<0.001	3.6	5.3	96.1
N5	0.5	0.5	1.5	24.4	<0.001	32.0	48.0	10.6
N6	0.5	0.5	1.0	26.3	<0.001	32.0	48.0	24.0
N7	0.5	0.5	0.5	36.6	<0.001	32.0	48.0	96.1

While each of the hyperparameters $\tilde{\sigma}_\alpha, \tilde{\sigma}_\beta, \tilde{\sigma}_\gamma$ can have an important impact on posterior inferences, they may be difficult to elicit or calibrate. One can use prior ESS graphically to assist in choosing these parameters. The idea is to compute the ESS for different combinations of the hyperparameters $\tilde{\theta}$, similar to Table 2. The ESS values are then plotted as a function of $\tilde{\theta}$. A practical problem is that one must first reduce the dimension of $\tilde{\theta}$ to $d = 2$ to allow one to construct a contour plot of ESS as a function of two hyperparameter values. As a general strategy, we suggest the use of simple restrictions on elements of θ . In this example, we will use $\tilde{\sigma}_\alpha = \tilde{\sigma}_\beta \equiv \tilde{\sigma}$, allowing us to plot ESS contours as a function of the two remaining hyperparameters $(\tilde{\sigma}, \tilde{\sigma}_\gamma)$. Fig. 1 shows the contours for $ESS = 0.5, 1.0, 2.0$, and 5.0 . From Fig. 1 one might, for example, decide to set $\tilde{\sigma}_\alpha = \tilde{\sigma}_\beta = 2.6$ and $\tilde{\sigma}_\gamma = 4.7$ to obtain $ESS = 1.0$.

TWO-AGENT DOSE-RESPONSE MODEL

We consider a design for a Phase I trial to determine an optimal dose combination $X = (X_1, X_2)$ of two cytotoxic agents.^[3] The toxicity probability at X is given by the 6-parameter model

$$\pi(X, \theta) = \frac{\alpha_1 X_1^{\beta_1} + \alpha_2 X_2^{\beta_2} + \alpha_3 (X_1^{\beta_1} X_2^{\beta_2})^{\beta_3}}{1 + \alpha_1 X_1^{\beta_1} + \alpha_2 X_2^{\beta_2} + \alpha_3 (X_1^{\beta_1} X_2^{\beta_2})^{\beta_3}}, \quad (2)$$

where all parameters in $\theta = (\alpha_1, \beta_1, \alpha_2, \beta_2, \alpha_3, \beta_3)$ are non-negative. Under this model, if only agent 1 is administered at dose X_1 , with $X_2 = 0$, as in a single-agent Phase I trial, then $\pi(X, \theta) = \pi_1(X_1, \theta_1) = \alpha_1 X_1^{\beta_1} / (1 + \alpha_1 X_1^{\beta_1})$ only depends on X_1 and $\theta_1 = (\alpha_1, \beta_1)$. Similarly, if $X_1 = 0$ then $\pi(X, \theta) = \pi_2(X_2, \theta_2) = \alpha_2 X_2^{\beta_2} / (1 + \alpha_2 X_2^{\beta_2})$ only depends on X_2 and $\theta_2 = (\alpha_2, \beta_2)$. The parameters $\theta_3 = (\alpha_3, \beta_3)$ characterize interactions that may occur when the two agents are used in combination. The model parameter vector thus is partitioned as $\theta = (\theta_1, \theta_2, \theta_3)$. Because

Fig. 1 Contour plots of ESS values for $\tilde{\sigma}$ (x-axis) and $\tilde{\sigma}_\gamma$ (y-axis). Dotted, solid, dashed, dashed-dotted lines show the plots of $ESS = 0.5, 1.0, 2.0$, and 5.0 , respectively

Phase I trials of combinations generally require that each agent previously has been tested alone, it is natural to obtain informative priors on θ_1 and θ_2 , but assume a vague prior on θ_3 . Denoting by $Ga(a,b)$ the gamma distribution with mean a/b and variance a/b^2 , the elicitation process (Thall et al., section 3)^[3] yielded the priors $\alpha_1 \sim Ga(1.74, 4.07)$, $\beta_1 \sim Ga(10.24, 1.34)$ for the effects of agent 1 alone, $\alpha_2 \sim Ga(2.32, 5.42)$, $\beta_2 \sim Ga(15.24, 1.95)$ for the effects of agent 2 alone, and $\alpha_3 \sim Ga(0.33, 0.33)$, $\beta_3 \sim Ga(0.0008, 0.0167)$ for the interaction parameters.

Since doses must be selected sequentially in Phase I trials based on very small amounts of data, an important question is what ESS may be associated with the prior. The ESS methods show that the overall $ESS = 1.5$. However, because informative priors on θ_1 and θ_2 were obtained and a vague prior on θ_3 was desired, it also is important to determine the prior ESS of each subvector. Applying the ESS computation methods yielded $ESS_1 = 547.3$ for θ_1 , $ESS_2 = 756.8$ for θ_2 , and $ESS_3 = 0.01$ for θ_3 . The small value for ESS_3 confirms that the prior on θ_3 reflects little information about the interaction of the two agents. The large numerical discrepancy between $ESS = 1.5$ and $(ESS_1, ESS_2) = (547.3, 756.8)$ is desirable. It reflects the fact that, for each $i = 1, 2$, " θ_i " has a very different meaning in the submodel $\pi_i(X_i, \theta_i)$ parameterized by θ_i alone versus its meaning in the full six-parameter model $\pi(X, \theta)$. See, for, example, Berger and Pericchi.^[4] From a geometric viewpoint, if $\pi(X, \theta)$ is thought of as a response surface varying as a function of the two-dimensional dose (X_1, X_2) , since the edges of the surface correspond to the submodels $\pi_1(X_1, \theta_1)$ where $X_2 = 0$ and $\pi_2(X_2, \theta_2)$ where $X_1 = 0$, the large values of ESS_1 and ESS_2 indicate that the locations of the edges were well known, while the small overall $ESS = 1.5$ says that otherwise very little was known about the surface. In practice, one would report ESS_1 , ESS_2 , ESS_3 , and ESS to the clinician from whom the priors were elicited. The clinician could then judge whether ESS_1 and ESS_2 are reasonable characterizations of his/her prior information about the single agents, and compare ESS to the trial's sample size. In this application, a trial of gemcitabine and cyclophosphamide for advanced cancer, the large values of ESS_1 and ESS_2 were appropriate since there was substantial clinical experience with each single agent, and the small overall ESS also was appropriate because no clinical data on the two agents used together were available and a sample size of 60 patients was planned.

CONCLUSION

An important area of practical application for the proposed prior ESS summaries is early phase clinical trials with small to moderate sample sizes. Concern about inappropriately influential prior information is one of the main impediments to a more widespread use of Bayesian

methods in clinical trials. By computing ESSs, one may avoid the use of an overly informative prior in the sense that inference is dominated by the prior rather than the data. Other uses of ESS values include interpreting or reviewing others' Bayesian analyses or designs, using the ESS values themselves to perform sensitivity analyses in the prior's informativeness, and calibrating the parameters of outcome-adaptive Bayesian designs.

The two examples illustrate four key features of our proposed method, namely that (i) ESS is a readily interpretable index of a prior's informativeness, (ii) it may be useful to compute ESSs for both the entire parameter vector and for particular subvectors, (iii) ESS values may be used as feedback in the elicitation process, and (iv) even when standard distributions are used, it may not be obvious how to define a prior's ESS.

Our ESS method described here is computationally complex. While the actual computational effort is negligible, the choice of a suitable ε -information prior and the evaluation of the prior-to-posterior distance require some problem-specific input from the investigator. That is, it is difficult to completely automate the ESS evaluation. However, the examples given here are intended to provide a basis for interested readers to compute and utilize prior ESS in their problems. A computer program, ESS_RegressionCalculator.R, to calculate the ESS for a normal linear or logistic regression model is available from the website <http://biostatistics.mdanderson.org/SoftwareDownload>.

Abstract

This entry presents an introduction to the Bayesian school of thought, providing definitions of its basic notions and core concepts and also discusses main ideas on how to use Bayesian analysis for clinical trial monitoring and sample size determination. Key components of the methodology will be demonstrated using examples from the biomedical field.

INTRODUCTION

The Bayesian approach to statistical inference has received increased attention in the scientific community over the past several decades because of the general framework it provides for incorporating new experimental evidence into scientific conclusions. Because of the core principles it rests upon, Bayesian analysis can be particularly useful in the field of biomedical research and development. There is an abundant literature on Bayesian analysis in general, as well as on Bayesian applications to the biopharmaceutical industry. Breslow's review, "Biostatistics and Bayes,"^[1] can serve as an introduction to the subject and links Bayesian analysis to numerous issues arising in clinical practice. Berry and Stangl^[2] provide an extensive collection of papers pertaining to the use of Bayesian methodology in health-related research. Among excellent general references are Berger,^[3] Bernardo and Smith,^[4] Press,^[5] and Gelman et al.^[6] Specific applications with suggested references include design of biomedical experiments,^[7] clinical trial monitoring,^[8–12] evaluation of drug pharmacokinetics and pharmacodynamics,^[13–15] planning trials with multiple endpoints,^[16] metaanalysis,^[17,18] and addressing ethical concerns associated with clinical trials.^[19]

OVERVIEW

In this entry, we will present an introduction to the Bayesian school of thought, providing definitions of its basic notions and core concepts. Key components of the methodology will be demonstrated using examples from the biomedical field. We also present main ideas on how to use Bayesian analysis for clinical trial monitoring and sample size determination. The literature cited contains many references to the other areas of application mentioned.

We will not attempt to discuss the differences between Bayesian and classical approaches in this entry. In the

authors' opinion, the two approaches address completely different sets of scientific questions and should be considered complementary. For a thorough comparison of both philosophies, see Berger,^[3] Carlin and Louis,^[20] or Gelman et al.^[6]

It should be noted that the implementation of Bayesian ideas has become increasingly prevalent in many areas of application because of recent advances in computational tools. Problems that were once just too difficult or too time-consuming to tackle from a Bayesian point of view are now becoming tractable. The last section of the entry contains a brief description of Bayesian computational methods.

BASIC NOTIONS AND BAYES THEOREM

Suppose a researcher conducts an experiment to test certain scientific beliefs, Q . Bayesian analysis provides a tool by which all prior knowledge about Q , $P(Q)$, can be combined with information about Q contained in data from an experiment, resulting in a posterior probability, or distribution of Q conditional on the data, $P(Q|\text{data})$. The core of this informational update is formed by Bayes' theorem. The theorem was first discovered by Rev. Thomas Bayes in the first half of the 17th century and published posthumously in 1763.^[21,22] In its simplest form it states that

$$P(Q|\text{data}) = \frac{P(Q) \times P(\text{data}|Q)}{P(\text{data})} \quad (1)$$

This result is a direct consequence of the laws of probability. In general, Q can be a statistical hypothesis, a distribution of a quantity of interest, or a parameter of this distribution. In the case of a parameter vector θ , Eq. 1 can be rewritten as:

$$\pi(\theta|y) = \frac{\pi(\theta) \times f(y|\theta)}{m(y)} \quad (2)$$

where y represents a vector of data, $f(y|\theta)$ is the likelihood, or conditional density, of the data given θ , $\pi(\theta)$ is the prior distribution of θ , and

$$m(y) = \int f(y|\theta)\pi(\theta)d\theta \quad (3)$$

is called the marginal distribution of Y . The following two examples demonstrate the use of Bayes' theorem for estimation purposes in both a discrete and a continuous case.

Example 1

Suppose a 40-year-old woman arrives for a routine obstetrics/gynecology visit and her physician performs a mammogram to test for the presence of breast cancer. Given a positive result of the test (the data), what is the chance that the patient indeed has breast cancer? Assuming that the woman has no family history of breast cancer and given the patient's age, the chance (prior probability) that she has the breast cancer is small—assume it is 0.1%. Let $\theta = 1$ if the cancer is present and $\theta = 0$ otherwise. Using Bayes' theorem,

$$\begin{aligned} P(\theta = 1 | \text{test is positive}) \\ = \frac{P(\text{test is positive} | \theta = 1) \times P(\theta = 1)}{P(\text{test is positive})} \end{aligned}$$

On the other hand,

$$\begin{aligned} P(\text{test is positive}) &= P(\text{test is positive} | \theta = 1) \\ &\quad \times P(\theta = 1) + P(\text{test is positive} | \\ &\quad \times \theta = 0) \times P(\theta = 0) \end{aligned}$$

Assuming further that the test procedure produces 5% false positives and 1% false negatives,

$$\begin{aligned} P(\text{test is positive}) &= 0.99 \times 0.001 + 0.05 \times (1 - 0.001) \\ &= 0.051 \end{aligned}$$

and, finally

$$\begin{aligned} P(\theta = 1 | \text{test is positive}) &= 0.99 \times 0.001 / 0.051 \\ &\cong 0.0194, \text{ or } 1.94\% \end{aligned}$$

In addition to illustrating the use of Bayes' theorem, this example highlights another important point. While having highly precise medical procedures (with high true-positive and low false-negative rates) is important, it is the “inverse” question—the chance of having the disease given a positive (or negative) result of the test—that is usually of the most interest. The Bayesian paradigm allows us to address this question directly. This seeming discrepancy between the precision of the diagnostic test and the posterior probability becomes especially pronounced for rare diseases (e.g., cancer, AIDS, and tuberculosis).

Example 2

Zyprexa® (olanzapine), a novel drug for the treatment of schizophrenia, was approved by the Food and Drug Administration (FDA) and European Medicinal Evaluation Agency (EMA) in September 1996. After approval, the sponsor, Eli Lilly and Company, was interested in collecting additional safety information. Given that serum prolactin elevations associated with older conventional neuroleptics were well documented in the literature, the sponsor wanted to estimate the impact of prolonged exposure to olanzapine on serum prolactin levels in a schizophrenic population. The mean prolactin level in a schizophrenic population taking olanzapine, θ , was chosen as the safety summary measure. The investigator's prior knowledge of θ was well represented by $N(\mu, \tau^2)$, with $\mu = 18.6$ and $\tau = 20.7$ ng/mL, based on the data previously summarized in the new drug application to the FDA. Let $y = (y_1, \dots, y_n)$ represent collected prolactin levels (ng/mL) from a prospective trial on n patients assessed after 6 months of drug exposure. For simplicity, we shall assume that $Y \sim N(\theta, \sigma^2)$, with $\sigma = 19.1$ ng/mL. Bayes' theorem yields a posterior distribution of θ that is also normal, with the mean $\mu(y)$ and variance v^2 given by:

$$\begin{aligned} \mu(\bar{y}) &= \mu \left(\frac{\sigma^2}{\sigma^2 + n\tau^2} \right) + \bar{y} \left(\frac{n\tau^2}{n\tau^2 + \sigma^2} \right) \text{ and} \\ v^2 &= \frac{\tau^2 \sigma^2}{n\tau^2 + \sigma^2} \end{aligned} \quad (4)$$

where $\bar{y} = n^{-1} \sum_{i=1}^n y_i$. Results from a multicenter double-blind clinical trial^[23] yielded $\bar{y} = 20.97$ ng/mL for $n = 144$ patients with a 6-month postbaseline serum prolactin measurement. The resulting posterior distribution of θ given the prior knowledge and the data is $N(20.96, 1.59^2)$. Hence the investigator could report with 95% probability that, given the currently available knowledge, the mean prolactin level in this patient population is contained between 17.84 and 24.08 ng/mL. Note the straightforward interpretation of this interval, born of conditioning on the data, in contrast to intervals constructed under the repeated sampling paradigm of classical statistics.

The marginal density $m(y)$ that appears in the denominator of Eq. 2 is sometimes called the *predictive distribution* of the data Y , which is also an important notion in Bayesian statistics. This distribution represents information about the value of an observation y given the prior knowledge and the likelihood function. Using the same idea as in Eq. 3, we can arrive at the posterior predictive distribution of new, yet-to-be-observed data, y_{new} , given observed data y . This type of distribution could be valuable, for example, in evaluating safety concerns of drugs under investigation.

Example 3

Clozapine is an atypical antipsychotic that has been associated with an increased risk of agranulocytosis, a

potentially fatal blood disorder defined as an absolute neutrophil count (ANC) $< 500 \mu\text{L}$ and the presence of symptoms of an infectious process. During clinical trials before the approval of olanzapine, there was interest in assessing whether olanzapine was also associated with an increased risk of agranulocytosis. Given the severity of the adverse event and the large amount of data being collected, it is reasonable to assume that physicians would want the ability to predict, for example, the probability of $\text{ANC} < 500$ for future patients conditional on all data collected up to a visit. To answer this question, one could average $f(y_{\text{new}}|\theta)$ with respect to the posterior distribution $\pi(\theta|y)$ that now plays the role of an updated prior, resulting in

$$p(y_{\text{new}}|y) = \int f(y_{\text{new}}|\theta)\pi(\theta|y)d\theta$$

Given this distribution, one could then calculate any probability of interest, for example,

$$p(y_{\text{new}} < 500|y) = \int_0^{500} p(y_{\text{new}}|y)dy_{\text{new}}$$

or report estimates such as 95% probability intervals, to aid in monitoring the safety of patients. One could even imagine setting objective bounds such as, say, $p(y_{\text{new}} < 500|y) > 0.0001$ to assist decisions of a monitoring board. Had this approach actually been used prior to approval, the physician monitoring the predictive distribution would have observed a constant decrease over time in the predictive probability of $\text{ANC} < 500$ as further evidence accumulated.

HYPOTHESIS TESTING

The problems of estimation and prediction are closely related to that of testing statistical hypotheses.

Example 4

Suppose researchers are now interested in testing the performance of olanzapine vs. a conventional neuroleptic competitor, haloperidol, in terms of the ability to reduce negative symptomatology. Such comparisons are often considered in pricing and reimbursement negotiations in European countries as well as for U.S. and Canadian formulary boards and marketing strategies worldwide. Consider a clinical trial where patients were assigned to olanzapine and haloperidol in a double-blinded fashion. The response variable of interest was assessed by the negative score from the Brief Psychiatric Rating Scale (BPRS). Let $Z = (z_1, \dots, z_n)$ and $H = (h_1, \dots, h_n)$ be the observations representing the difference between endpoint and baseline of scores collected from patients on olanzapine

and haloperidol, respectively (here, we assumed for simplicity that an equal number of patients was assigned to each treatment). Defining $d_i = z_i - h_i$, $i = 1, \dots, n$, suppose that $D = (d_1, \dots, d_n) \sim f(d|\theta)$, where θ represents the difference between mean change BPRS negative scores (endpoint minus baseline) of olanzapine and haloperidol, respectively. The test of the hypothesis $H_0: \theta \geq 0$ vs. $H_1: \theta < 0$ is of primary interest.

In the Bayesian paradigm, the choice between H_0 and H_1 is based upon the so-called *posterior odds ratio*:

$$\frac{P(H_1|\text{data})}{P(H_0|\text{data})} = \frac{P(\text{data}|H_1)}{P(\text{data}|H_0)} \times \frac{P(H_1)}{P(H_0)} \quad (5)$$

which represents the evidence in favor of H_1 vs. H_0 after observing the data. The ratio of $P(H_1)$ to $P(H_0)$ is called the *prior odds*. The ratio of posterior to prior odds,

$$B_{10} = \frac{\{P(H_1|\text{data})/P(H_0|\text{data})\}}{\{P(H_1)/P(H_0)\}} \quad (6)$$

is called the *Bayes factor*. It comprises a measure of how much evidence in favor of H_1 has changed after the data have been observed. Note that it represents the *change* in evidence, not an absolute measure of support for a hypothesis; interpreting Bayes factor as the latter can be very misleading.^[24,25]

Consistent with the literature, we will assume that the average of $n = 65$ collected observations, $\bar{D}$, is distributed as $N(\theta, \sigma_D^2/n)$, with $\sigma_D^2 = 11.0$, and that $\theta \sim N(\mu, \tau^2)$, with $\mu = -0.77$ and $\tau^2 = 17.53$. Note that, a priori, $P(H_0) = P(\theta \geq 0) = 0.428$ and $P(H_1) = P(\theta < 0) = 0.572$, and hence the prior odds of the investigator's beliefs about olanzapine's reducing negative symptoms, as compared to haloperidol, are $0.572/0.428 = 1.34$. Suppose that observed data from the prospective clinical trial yields $\bar{d} = -0.18$. The posterior distribution of θ [see Eq. 4] is normal, with the mean equal to -0.186 and the variance equal to 0.168 . Hence the posterior probabilities of the hypotheses are $P(H_0|\text{data}) = P(\theta \geq 0|\text{data}) = 0.326$ and $P(H_1|\text{data}) = P(\theta < 0|\text{data}) = 0.674$, yielding the posterior odds ratio $P(H_1|\text{data})/P(H_0|\text{data}) = 2.07$. We conclude that, based on the prior information and the evidence provided by the data, olanzapine is 2.07 times more likely than haloperidol to reduce negative symptoms as measured by BPRS. Note that the Bayes factor here is 1.55, thus implying that, after conducting the trial, the investigators' beliefs about the odds of olanzapine's reducing negative symptoms, as compared to haloperidol, have increased by 1.55.

The Bayesian approach to model selection and hypothesis testing was pioneered by Jeffreys,^[26] who used it to choose among competing scientific theories. Kass and Raftery^[27] provide an excellent review of the uses of Bayes factors for model selection in a variety of scientific applications.

CHOICE OF PRIOR DISTRIBUTIONS

The process of quantifying knowledge prior to decision making or future experimentation such as in the prolactin experiment is a struggle faced by *all* statisticians. Prior distributions are probabilistic expressions of knowledge possessed *prior* to conducting an experiment. It is perhaps easiest to think about prior distributions as falling into two broad categories, classified according to how the prior information is going to be incorporated into a distributional form or the purpose of the prior. The first category describes the scenario in which it is desirable to measure and incorporate an expert's uncertainty into posterior inference. The second category is characterized by situations in which one does not want to (or cannot) represent an expert's opinion, often referred to as "letting the data speak for themselves."

Scenarios in which one desires to incorporate prior information may arise, for instance, in a situation in which historical data exist and/or an expert opinion is available. In this case, the prior distribution can be formed by direct approximation from the available data or expert opinion. Alternatively, one can first choose a reasonable parametric functional form for the shape of the prior and then estimate or elicit the parameters for this distribution. For example, suppose that a normal distribution was deemed adequate to summarize the prior knowledge. One could then elicit or estimate information such as the center and the upper or lower quartile (quartiles are usually easier to assess than the standard deviation). The elicitation process boils down to a measurement problem in which the unit of measurement is a probability. Because experts are rarely trained in probability theory (because they can be anyone possessing the knowledge prior to an experiment), the elicitation process can be a challenging task, and the elicited information should be checked often for consistency. In the case of the normal distribution, for instance, it may be useful to gather information about *both* quartiles and perhaps some other percentiles of the distribution. For an excellent review and recommendations for eliciting prior distributions for biomedical applications, see Kadane and Wolfson,^[28] O'Hagan,^[29] and Chaloner.^[30] For some standard ways to approximate prior distributions in general, see, for example, Berger.^[3]

A common criticism of these types of priors is their very nature: they are based on subjective expert opinion or subjectively chosen data and thus can change, should another pool of experts or a set of data be chosen. For instance, one certainly wants to avoid the scenario in which an overzealous investigator overestimates the performance of a treatment and thus has an undue effect on the posterior conclusions drawn. To address this problem, Spiegelhalter et al.^[31,32] suggested considering a series of "experts" representing a skeptic, a clinician, the interest of a regulatory agency, and an uninformed or neutral individual. Another way of addressing this criticism is to extend the single

prior to a reasonable class of priors and to investigate the sensitivity of the final conclusion of the experiment to the class of priors chosen. See, for example, Greenhouse and Wasserman,^[11] Lavine et al.,^[33] and Berger^[34,35] for a discussion of issues related to prior robustness. Another argument to keep in mind is that, as the data from the experiment accumulate, the effect of the prior becomes increasingly less pronounced on the posterior. Hence for large sample sizes, usage of a prior becomes merely a way of invoking Bayesian machinery, and its particular choice become inessential.

The elicitation process may also result in a prior that does not prefer any single value of a parameter over any other. This scenario meets the objective of the first category of priors (thus incorporating expert opinion), although it is perhaps more common under the second category (where the impact of the prior information on the posterior is minimized). These types of priors are often called *noninformative* or objective. For example, in a case of a binomial experiment with parameters n and p , a possible noninformative prior on p is a uniform distribution on $[0,1]$. In the case of a normal distribution with a known variance, a reasonable noninformative prior for the mean parameter is a constant over the whole real line. Note that this prior is improper, in the sense that it does not integrate to a finite value, but this fact poses no problem for estimation purposes. Different statistical arguments can give rise to different noninformative priors. If the variance of the normal is unknown, for instance, reasonable choices of noninformative priors are $\pi_1(\theta, \sigma) = 1/\sigma^2$ and $\pi_2(\theta, \sigma) = 1/\sigma$. The former is an example of the so-called Jeffreys prior, based on the Fisher information matrix.^[26] The latter arises from the arguments of Bernardo^[36] and represents a so-called reference prior for the problem. A summary of various types of noninformative priors and corresponding posterior distributions is provided in Box and Tiao.^[37] For a general discussion of noninformative priors, see, for example, Berger,^[3] Bernardo and Smith,^[4] Carlin and Louis,^[20] and Gelman et al.^[6] Kass and Wasserman^[38] provide a summary of the vast literature in which theoretical and practical considerations of noninformative prior distributions are explored and debated.

When employing noninformative priors, it is important to keep in mind that no prior can literally be noninformative or objective; it must be judged as such on a relative basis. The "noninformativeness" it represents is always specific to the information criteria being used and to the scientific and statistical structure of a particular experimental problem. For an insightful discussion of objectivity in the role of science, see Howson and Urbach.^[39] Noninformative priors have long been viewed as attractive and will continue to be important as Bayesian assessments and interpretations become more prevalent in regulatory settings, because of the minimal role they play in the posterior distribution relative to the data.

In trying to accomplish either of the goals associated with the two categories of priors, sometimes priors of a specific functional form are chosen for ease of computation. In “Example 2,” the use of normal data $Y \sim N(\theta, \sigma^2)$, with fixed σ and $N(\mu, \tau^2)$ prior distribution for θ , resulted in a normal posterior distribution for θ , $N(\mu(y), v^2)$. This example illustrates the property of *conjugacy*, in which the posterior distribution follows the same parametric form as the prior distribution. As another example consider binomial data Y resulting from n Bernoulli trials with success probability p . A *conjugate* family of priors for p corresponding to this scenario is a Beta family, $B(a, b)$, where $a, b > 0$ are parameters of the distribution. Specifically, if $Y \sim \text{Binomial}(n, p)$, and a priori $p \sim B(a, b)$, then the posterior distribution for p is $B(a + y, b + n - y)$. More generally, we know that if we sample from the exponential family and our prior distribution is also a member of the exponential family, then the posterior, in turn, will also be from the exponential family. This knowledge removes the necessity to explicitly calculate the marginal density while still allowing the prior to be updated with information contained in the data. Clearly, mathematical convenience should not dictate the form of the prior distribution. However, *mixtures* of conjugates are often mathematically convenient and allow for approximation of prior beliefs in a more flexible manner. For a discussion of conjugate priors, as well as mixtures of conjugate priors and families, see, for example, Bernardo and Smith.^[4]

CLINICAL TRIAL MONITORING

In the standpoint of regulatory, medical, and budget constraints, most controlled clinical trials have a fixed sample size chosen prior to start-up based upon the expected magnitude of drug effectiveness and adverse event profile. Unfortunately, the precision of knowledge available regarding these factors is often minimal prior to conducting a trial, and thus the choice of the sample size may depend on possibly false assumptions. To address the ethical aspects of this dilemma and to assess the possibility of stopping a trial early, partially collected data from a clinical trial are often analyzed during interim analyses. Repeated testing of the null hypothesis in a classical setting leads to an accumulation of the Type I error rate.^[40] Methods arising from the works of Pocock,^[41] O’Brien and Fleming,^[42] Lan and DeMets,^[43] and Jennison and Turnbull^[44] suggest various criteria for adjusting significance levels at interim and at final analyses to address the problem. The main shortcoming of all these approaches is the fact that the final inference depends on whether or not one has entertained the possibility of rejecting the null hypothesis early at an interim analysis, i.e., the stopping rule selected for the trial. In other words, the same set of data may lead to a different conclusion about the significance of the observed results, depending on whether one has looked at part of the data

at an interim analysis. This concept is usually found to be counterintuitive by many practitioners. Bayesian inference, on the other hand, depends only on the observed data and not on the stopping rule used. An excellent discussion of this issue is presented in Berger and Wolpert.^[45] From a Bayesian perspective, one could look at the data as often as necessary without the risk of affecting the final conclusion. The essence of how this monitoring can be carried out may be found in many references (see, for example, Ref. [46] or Ref. [10]) and is demonstrated here through an example.

Recall the setting of “Example 4.” Under the assumptions of the example, the posterior distribution of d , the true treatment difference between olanzapine and haloperidol with respect to negative symptoms, given n observed pairs of observations, is normal $N(\mu(\bar{d}), \rho^{-1})$, with

$$\mu(\bar{d}) = \mu \left[\frac{\sigma^2/n}{(\tau^2 + \sigma^2/n)} \right] + \bar{d} \left[\frac{\tau^2}{(\tau^2 + \sigma^2/n)} \right] \quad \text{and} \\ \rho = \frac{n\tau^2 + \sigma^2}{\tau^2\sigma^2}$$

Note that, in this setting, smaller values of d —say, $\{d < d_1\}$ —would speak to the advantage of olanzapine (i.e., inferiority of haloperidol), while larger values of d —say, $\{d > d_2\}$ —would speak to the advantage of haloperidol (i.e., inferiority of olanzapine). Then the set $\{d_1 < d < d_2\}$ indicates a region of clinical equivalence of the two drugs (in some instances, one may be interested in setting $d_1 = d_2$). When comparing to a proven active control, it is reasonable to suggest that the trial should be stopped early if either treatment is found no worse than the competitor drug with high probability. This requirement means that we would stop after m observed pairs if either posterior probability

$$P(d < d_2 | D_1, \dots, D_m) > 1 - \varepsilon_1 \quad \text{or} \\ P(d > d_1 | D_1, \dots, D_m) > 1 - \varepsilon_2$$

where ε_1 and ε_2 are prespecified, small, positive constants. These requirements translate into the following regions for $\mu(\bar{d})$, $\bar{d} = m^{-1} \sum_{i=1}^m d_i$:

$$\mu(\bar{d}) < d_2 + \rho^{(-1/2)} \phi^{-1}(\varepsilon_1) \quad \text{or} \\ \mu(\bar{d}) < d_1 - \rho^{(-1/2)} \phi^{-1}(\varepsilon_2)$$

That is, one is to stop after m observations if either of the foregoing conditions is satisfied. Here, $\Phi^{-1}(\varepsilon)$ is the ε th percentile of the standard normal distribution.

SAMPLE SIZE DETERMINATION

Because Bayesian analysis allows frequent monitoring of the data being collected, the choice of the sample size prior to conducting an experiment is not necessary. Under the Bayesian paradigm, one can evaluate the decision to

discontinue an experiment with each look at the data. However, considering that all scientists have budgetary constraints and must plan for future expenditures associated with experiments, the choice of the sample size is often required.

A formal approach to sample size determination in Bayesian analysis requires the use of decision-theoretic framework.^[3] The use of this framework requires the introduction of a statistical loss function that specifies a penalty for errors in estimation and a cost of obtaining sampling information. Minimization of the loss function results in the optimal sample size. Here, however, we will present some practical ideas on how to choose the sample size without explicitly specifying loss functions, because the general concept of the latter may seem unnatural to the practitioner. In particular, these ideas rely upon the notion of a so-called highest-posterior-density (HPD) set. Their application to determining sample sizes for binomial proportions, multinomial and normal sampling, can, for example, be found in Adcock,^[47,48] Pham-Gia and Turkkan,^[49] and Joseph et al.^[50] Formally speaking, an HPD set with coverage probability $(1 - \alpha)$ for a posterior density $\pi(\theta|x)$ is defined as a set $A = \{\theta \in \Theta\}$ such that $\int_A \pi(\theta|x) d\theta = 1 - \alpha$, and such that the length of A , $l(A)$, or in higher dimensions, volume, is minimal. For instance, in “Example 2,” the interval [17.48, 24.08] for mean level of serum prolactin (ng/mL) in a schizophrenic population was actually a 95% HPD set.

Typically, an HPD set of length l and coverage probability $(1 - \alpha)$ is sought. Because such a set depends on the data X , which are not known before the experiment, one of the ideas is to average across all possible data. *Average coverage criterion* (ACC) proposes to choose the minimum number of observations, n , satisfying

$$\int_{\mathfrak{N}} \left\{ \int_{A(x,n)} \pi(\theta|x) d\theta \right\} f(x) dx \geq 1 - \alpha \quad \text{and} \quad l(A(x)) = l$$

where $f(x)$ is the data density, $\mathfrak{N}$ is the observational space, and $A(x,n)$ represents the HPD set. Alternatively, one could use an *average length criterion*. In this case, for each data point x in $\mathfrak{N}$, one would first find an HPD set of length $l^*(x,n)$ with coverage probability $(1 - \alpha)$, and then find the minimum n satisfying $\int_{\mathfrak{N}} l^*(x,n) f(x) dx \leq l$. Another alternative, the *worst outcome criterion*, ensures that the coverage probability is at least $(1 - \alpha)$ and $l(A)$ is at most l , regardless of the observed data, by requiring minimum n to be chosen so that

$$\inf_{x \in \mathfrak{N}} \left\{ \int_{A(x,n)} \pi(\theta|x) d\theta \right\} \geq 1 - \alpha \quad \text{and} \quad l(A) = l$$

In the case of “Example 2,” the posterior distribution is normal, and thus $l(x,n)$ depends only on n and not on x .

In addition, $\int_{A(x,n)} \pi(\theta|x) d\theta$ also does not depend on x . Hence all three criteria offer the same answer:

$$n \geq \left(\frac{4}{l^2} \right) \sigma^2 \Phi^{-1} \left(1 - \frac{\alpha}{2} \right) - \frac{\sigma^2}{\tau^2}$$

where $\Phi^{-1}(1 - \alpha/2)$ represents the $(1 - \alpha/2)$ th percentile of the standard normal distribution. A more computationally challenging scenario arises in the case of the binomial data with Beta (conjugate) priors. Joseph et al.^[50] considered an example of a randomized two-arm parallel clinical trial designed to compare two drugs, warfarin and low-molecular-weight heparin, for the treatment of deep vein thrombosis (DVT). Equal numbers of patients, n , were to be randomized to each treatment. Suppose p_1 and p_2 are DVT rates under warfarin and heparin, respectively. Joseph et al.^[50] assumed that the number of patients who would develop DVT in the trial were independent binomial random variables with respective parameter sets (p_1, n_1) and (p_2, n_2) . Based on the previous data, the authors chose Beta(3,11) and Beta(11,52) priors for p_1 and p_2 , respectively. Using $\alpha = 0.05$ and $l = 0.05$ yielded $n_{\text{ACC}} = 1800$, $n_{\text{ALC}} = 1770$, and $n_{\text{WOC}} = 3075$. Computation of these sample sizes were based on the exact likelihood and were performed by drawing Monte Carlo samples from the posterior distribution.^[51–53] The software implementing these computations in S-plus can be found on the World Wide Web (WWW) at the following address:

<http://www.epi.mcgill.ca/~web2/Joseph/software.html>

BAYESIAN COMPUTING

Implementation of Bayesian methodology requires the computation of posterior and marginal distributions that involve integral expressions. The use of conjugate priors is very appealing from that perspective because it results in closed-form expressions for the posterior. In all other cases, one can use methods based on either analytic approximations of Taylor’s theory (see, for example, Schwarz,^[54] Tierney and Kadane^[55]) or numerical quadratures (Naylor and Smith,^[56] Dellaportes and Wright^[57,58]), importance sampling (Hammersley and Handscomb,^[59] Berger^[3]), and Markov chain Monte Carlo techniques (Geman and Geman,^[60] Tanner and Wong,^[61] Gelfand and Smith,^[62] Gamerman,^[63] Cowles and Carlin^[64]). Development of these computational methods has received a lot of attention in recent years and is an active field of current research.^[65]

There is an abundant quantity of available software that implement some of the preceding ideas. Interested readers are referred to Goel^[66] and to Carlin and Louis,^[20] who provide an extensive overview of the currently available Bayesian software. Here, we would like to mention a few popular programs that, in the authors’ view, are likely to be used by scientists in the biomedical field. One such

package, Bayesian inference Using Gibbs Sampling (BUGS), developed by D. Spiegelhalter, A. Thomas, N. Best, and W. Gilks, is built upon the use of Markov chain Monte Carlo techniques. The software and a set of manuals, along with many references on theory and application of the tool, is available through the WWW site of MRC Biostatistics Unit (Cambridge, UK) at:

<http://www.mrc-bsu.cam.ac.uk/bugs/Welcome.html>

for Unix, DOS, and Windows platforms. "Sbayes," developed by L. Tierney at the University of Minnesota, utilizes Laplace approximations for posterior evaluations and consists of a set of functions written in the S programming language. This program is available at:

<http://lib.stat.cmu.edu/S/sbayes>

Both "BUGS" and "Sbayes" are free software. Commercially available packages, SAS and BMDP, also allow some Bayesian computation within their procedures PROC MIXED and BMDP-5V, respectively. These procedures are targeted for the analysis of mixed-effects models,^[67] often used for the analysis of clinical trials, and other scenarios that give rise to repeated-measures data.

ACKNOWLEDGMENTS

The authors wish to thank their colleagues, J.W. Seaman, V. Arora, and J.D. Helderbrand, for many insightful comments and discussions that led to the improvement of both the structure and the focus of the manuscript.

Abstract

Bayesian statistical methodology has been used for more than 10 years in medical device clinical trials for premarket submissions. In this entry, two major ways of using a Bayesian approach in medical device clinical trials will be discussed in detail with examples. Bayesian methods can be used for adaptive designs and for incorporating prior data.

Keywords: Adaptive design; Hierarchical model; Predictive distribution; Historical data; Operating characteristics.

INTRODUCTION

A medical device is defined in the United States (U.S.) Food, Drug, and Cosmetic Act as “an instrument, apparatus, implement, machine, contrivance, implant, in vitro reagent, or other similar or related article ... which does not achieve its primary intended purposes through chemical action within or on the body of man or other animals and which is not dependent upon being metabolized for the achievement of its primary intended purposes.”

In the United States, medical devices are regulated by the Food and Drug Administration (FDA) Center for Devices and Radiological Health (CDRH). Medical devices are classified as high, medium, or low risk, and there are two basic pathways for marketing approval in the United States. The first pathway, for higher risk and new technologies, requires demonstration of reasonable assurance of safety and effectiveness of the device. This type of regulatory pathway is called a premarket approval (PMA). The second pathway, mainly for low and medium risk devices, requires demonstration of “substantial equivalence” to a device that is already legally marketed. This type of pathway is called a 510(k) after its section number of the U.S. Food, Drug, and Cosmetic Act.

Since the late 1990s, CDRH has been encouraging the use of Bayesian statistical methods to support approval of medical devices. CDRH issued a guidance document on the use of Bayesian methods in 2010 as well as a guidance in 2016 on adaptive clinical trials and many of which use Bayesian methods. Because medical devices are usually engineered products with many opportunities

for incremental improvement, there are often prior data that can be used. The effects of modifications to a medical device are usually better understood because devices often have a localized known mechanism of action. Therefore, the Bayesian paradigm of learning from evidence as it accumulates is well suited to medical device development.

In the Bayesian framework, prior knowledge about parameters is summarized by the prior density $p(\theta)$, and the information in the observed data is contained in the likelihood $p(y|\theta)$. Using Bayes' theorem, the posterior density for the parameters can be written as

$$p(\theta|y) = p(y|\theta)p(\theta)/p(y).$$

Since $p(y)$ can be regarded as a normalizing constant, we have that

$$p(\theta|y) \propto p(y|\theta)p(\theta).$$

That is, the posterior is proportional to the product of the prior and the likelihood. A prior with a high influence on the posterior is said to be “informative.” If there is a large amount of observed data, or if the prior is not informative, then the posterior is primarily determined by the likelihood.

In the following sections, two major ways of using a Bayesian approach in medical device clinical trials will be discussed in detail with examples. One approach uses adaptive design; the other approach incorporates existing prior data.

PLANNING A BAYESIAN CLINICAL TRIAL

Prior Distribution

The prior distribution is a key part of Bayesian inference and represents the information about a parameter that is combined with the probability distribution of new data to yield the posterior distribution, which in turn is used for inferences and decisions. Prior distributions are probabilistic expressions of information possessed prior to conducting a new trial. Prior distributions can be informative or (relatively) non-informative.

Informative prior distributions give preferences to some values of the parameter of interest as being more likely than others. Informative priors may be utilized when historical data related to the device under study are present. Generally, for any previous studies to be considered appropriate as prior information, they should be similar to the proposed study in a number of factors. The process of quantifying prior information for the proposed trial may be challenging. Often, however, the prior distribution can be formed by direct approximation from the available data. Alternatively, one can first choose a reasonable parametric functional form for the shape of the prior and then estimate or elicit the parameters for this distribution.

A non-informative prior distribution, also referred to as a vague or flat prior, may be used when one does not want to use available prior information, or prior information from the previous studies is not available. For example, in the case of a binomial experiment with parameters n and p , a possible non-informative prior on p is a uniform distribution on $[0,1]$. In the case of a normal distribution with a known variance, a reasonable non-informative prior for the mean parameter is a constant over the whole real line or a normal distribution with a large variance.

Determining the Sample Size

The sample size of a Bayesian clinical trial depends on variability of the sample, prior data, assumed statistical model and prior distributions of model parameters, and decision criteria for various actions. Unlike traditional frequentist design, there is usually no closed solution for the sample size. Instead, extensive simulation is usually required to determine the sample size.

To begin the process of determining the sample size for a Bayesian study, often a minimum sample size is first specified based on clinical considerations—for example, sufficient number of patients needed to assess the safety profile of the investigational device. Then, based on available resources, such as the feasibility of enrolling patients and available funding, a maximum sample size is determined. From here on, simulations under various scenarios of the design parameters may be performed to see how potential sample sizes meet certain predetermined operating characteristics, such as type I error rate and

power. The determination of sample size is interrelated with the choice of design parameters.

Assessing the Operating Characteristics of a Bayesian Design

Due to the inherent complexity in the design of a Bayesian clinical trial, specifically when prior data are used and/or a wide variety of adaptations are planned, a thorough evaluation of the operating characteristics is of paramount importance. Evaluation of the operating characteristics usually includes:

- type I error rate
- power
- average sample size and
- if applicable, probability of stopping at each interim look.

In a regulatory environment, it is usually necessary to control type I error rate at an appropriate level. In general, when no prior data are used, the type I error rate is controlled at the customary frequentist level. When prior data are used, the type I error rate is often controlled at a higher level, with consideration given to the credibility of the prior data and the knowledge of potential risk–benefit profile of the investigational device.

An adequate characterization of the operating characteristics of any particular trial design usually needs extensive simulations. Simulations are performed under various more-or-less plausible scenarios of design parameters, evaluating the desirability of the operating characteristics. The process may be iterative, in the sense that sample size, any interim analysis rule, study success criteria, and priors may need to be adjusted many times to achieve the acceptable operating characteristics.

ANALYZING A BAYESIAN CLINICAL TRIAL

Summary of the Posterior Distribution

Conclusions from a Bayesian clinical trial are usually based on the posterior distributions of the parameters of interest. The posterior distribution contains all information from the prior distribution as well as the information from the current trial via the likelihood function. The posterior distribution is usually summarized with posterior mean, standard deviation, and credible interval. Graphical representations of the appropriate distributions are also helpful.

Hypothesis Testing and Interval Estimation

Statistical inference may include hypothesis testing, interval estimation, or both. For medical device clinical trials, the hypotheses are usually one-sided. Therefore, for Bayesian

hypothesis testing, the posterior probability of interest is that the treatment effect is less or greater than a prespecified value. If this posterior probability is greater than a threshold value (for example 97.5%), the null hypothesis is rejected.

Bayesian interval estimates are based on the posterior distribution and are called credible intervals. If the posterior probability that a parameter of interest lies in an interval is $x\%$, then this interval is called an $x\%$ credible interval. Two types of frequently reported credible intervals are highest posterior density intervals and central posterior intervals. A credible interval can also be used for testing a hypothesis in the same way that a confidence interval is used.

Interim Analysis

Interim analyses can be performed to make preplanned adaptations to a trial. Some examples that often occur in medical device trials are interim assessments to decide whether to stop accrual into a trial, whether to stop the trial for success, or whether to stop the trial for futility (additional adaptations are discussed in a later section). For a regulatory submission (as well as good clinical trial practice), the methodology and analyses employed for such interim assessments should be prespecified in the trial's design. For many interim assessments, the (posterior) predictive distribution is useful. The posterior predictive distribution of a new observation, y_{new} , from likelihood $p(y|\theta)$, when y_{old} are data already observed in the trial is

$$p(y_{\text{new}}|y_{\text{old}}) = \int p(y_{\text{new}}|\theta)p(\theta|y_{\text{old}})d\theta.[1]$$

From the predictive distribution, predictive probabilities may be obtained to make interim decisions about the trial.

To stop accruing patients into a trial based on interim data, the predictive probability of study success can be used as a decision criterion. For example, at an interim analysis, the predictive distribution for patients with incomplete follow-up is derived; then the predictive probability of study success is calculated with respect to all accrued patients. If this predictive probability is sufficiently high, the trial may stop accrual and continue follow-up on all patients. The final analysis is performed when all accrued patients have completed the follow-up. Such interim assessments for stopping accrual may be especially useful for trials with long follow-up and slow accrual.

To stop a trial for success based on interim data, both the posterior probability of treatment effect and the predictive probability of study success can be used as criteria. The posterior probability of treatment effect is calculated based on data from enrolled patients with complete follow-up; the predictive probability of study success is calculated with respect to all accrued patients with complete and incomplete follow-up. In general, the criterion to claim

study success is higher using the predictive probability than using the posterior probability because of additional model assumptions required to relate the outcomes for patients with complete follow-up to outcomes to be observed.

For an interim assessment to stop a trial for futility with a planned maximum sample size, one might use the predictive distribution for enrolled patients with incomplete follow-up and for patients to be enrolled within the maximum of the planned sample size. Then, the predictive probability of study success is calculated with respect to the maximum planned sample size. If this predictive probability is too low, the trial may stop for futility.

Sensitivity Analysis

In Bayesian clinical trials, a sensitivity analysis is usually conducted to investigate the effects of deviations from the statistical model and its assumptions on the main results of the trial. Sensitivity analyses might include investigations of:

- deviations from the distributional assumptions;
- alternative functional forms for the relationships in the model;
- alternative prior distributions;
- alternative “hyper prior” parameters in hierarchical models;
- deviations from any “missing at random” assumptions for missing data;
- alternative design parameters, accrual rate, correlations among longitudinal outcomes, etc.

A clinical trial result is considered to be robust if the study conclusions are approximately the same for most of the possible sensitivity analyses.

Model Checking

Model checking is especially important in a Bayesian analysis due to the complexity of the models employed. A tool frequently used in Bayesian model checking is the posterior predictive distribution of hypothetical observations from the trial, under the assumptions of the current model. One can generate new, hypothetical data from the posterior predictive distribution to see how well it “matches” observed data from the trial. The assessment of how well the posterior predictive data match the observed data can be made using the “Bayesian p value,” which is the posterior predictive probability of observing a result at least as extreme as what was observed in the trial.^[1]

In addition, Bayesian deviance measures such as deviance information criterion (DIC)^[2] can be used for model choice by comparing the fit of one model over another. It is calculated as the posterior mean of the model deviance minus the effective number of parameters in the model (p_D), where the effective number of parameters is the decrease in deviance expected from estimating the

parameters of the model. pD can be estimated as the posterior mean of the deviance minus the deviance evaluated at the posterior mean of the parameters.^[1] The minimum DIC estimates the model that will make the best short-term predictions. An useful application of DIC is to compare the fit of a normal random effects distribution to that of a (truncated) Dirichlet process mixture model, if a more flexible random effects distribution is desired.^[3] Alternatively, two models may be compared using Bayes factors.

For additional details on planning and analyzing a Bayesian study, the reader should consult the texts by Carlin and Louis,^[4] Gelman et al.,^[1] and FDA guidances.^[5,6]

BAYESIAN ADAPTIVE DESIGN

The Bayesian approach can offer flexibility in adapting important aspects of a study design, including the sample size, subject allocation ratio, number of treatment arms, etc.^[7] These parameters can be adjusted as information about the performance of the device is accrued, and this can potentially result in shorter trial duration and smaller size. Most importantly, the Bayesian approach allows for the construction of likelihood models that use information obtained at earlier follow-up time points to predict endpoints at later time points. Such use of predictive distributions can be particularly useful for clinical studies in which the follow-up period is long. Adaptive designs may require considerable planning but can pay off enormously. The potential advantages are illustrated in the following paragraphs.

Here, an example of a hypothetical trial to demonstrate superiority of an investigational device to control therapy is presented. Subjects are randomized to the investigational and control devices with a ratio of 2 (investigational) to 1 (control). The primary endpoint of the study is a composite of safety and effectiveness outcomes at 24 months, which classifies patients as an overall success or not. Additionally, interim measurements of the composite primary endpoint are available at 3, 6, and 12 months. To determine the operating characteristics, the success rate for the control therapy is assumed to be 75% (P_C), and for the investigational device, it is assumed to be 85% (P_T). Based on clinical safety considerations, the minimum sample size for the study is 300 subjects. And the maximum sample size is 800 based on the available financial resources. The recruitment rate is projected to be 20 subjects per month.

This Bayesian adaptive trial implements two types of adaptations. The first is sample size adaptation. The first potential sample size adaptation takes place when 300 subjects have been enrolled into the study, with additional potential adaptations every time when 50 subjects are accrued. At each interim analysis for sample size adaptation, one decides whether to stop accrual or to continue. This decision is based on modeling all the follow-up data available, including follow-up data at 3, 6, 12, and

24 months. If the predictive probability of trial success given the enrolled subjects exceeds a prespecified value (chosen as 0.8 for this trial), then the trial stops accrual; otherwise, enrollment will continue to the next stage.

The second adaptation is to potentially stop the trial for an early claim of study success. This adaptation occurs after the trial stops accrual, and it has four planned looks at 0, 6, 12, and 18 months. These looks will be conducted only if at least 150 patients have 24 months of follow-up data. Study success will be claimed if the predictive probability exceeds 0.995 at one of the interim looks. If study success is not claimed at an interim look, then when complete follow-up data are available for all enrolled subjects, study success will be claimed if the posterior probability exceeds 0.985.

The operating characteristics of this Bayesian adaptive trial can be approximated using simulations. To generate patient-level data, patient outcomes at 0, 3, 6, 12, and 24 months are assumed to be correlated. Based on the results from historical trials, the responses for a subject are assumed to follow a Markov chain model—i.e., given the observation at time $(t - 1)$, the observation at time t does not depend on previous observations. The model requires the specification of transition probabilities (see Table 1). Different probabilities of 24-month success can be generated by varying the transition probabilities. The prior distributions were assumed to be non-informative. The data for each subject can then be generated using the beta-binomial distribution. This process was then repeated 10,000 times and the obtained operating characteristics for the design are shown in Table 2.

As can be seen from column 2 of Table 2, study power is over 80% when the 24-month success rate in the treatment group is 85% (P_T). As can be seen from the last row, the type I error rate is 2.1% when $P_T = P_C = 0.75$. Table 2 also shows the average sample size, average number of subjects with complete follow-up at the time trial success is claimed, and the trial duration.

Table 1 Transition probabilities

	Success	Failure
Success at 3 months	0.63	0.37
3-Month success to 6 months	0.9	0.1
3-Month failure to 6 months	0.46	0.54
6-Month success to 12 months	0.9	0.1
6-Month failure to 12 months	0.311	0.689
12-Month success to 24 months	0.9	0.1
12-Month failure to 24 months	0.311	0.689

Table 2 Operating characteristics of proposed Bayesian design

Treatment effect (P_t)	P (trial success)	Average sample size	Average complete follow-up	Trial duration (months)
0.87	0.933	548	363	42.2
0.86	0.884	554	395	43.8
0.85	0.806	562	431	45.6
0.84	0.717	571	466	47.3
0.83	0.606	582	501	49.1
0.75	0.021	694	692	58.6

BAYESIAN DESIGN FOR INCORPORATING HISTORICAL DATA

One of the motivations for using Bayesian methods for medical device clinical trials is the capability to incorporate prior data. Medical device technology develops rapidly, and new versions of a device are developed in an iterative manner. Therefore, if a device is used as a concurrent active control in a study, data from a prior study could be used to augment the active control data. Another situation is where prior data may be available from both the treatment and control devices in the target population. With appropriate downweighting, this prior information might be used to augment a new study.

There are usually several ways to incorporate prior data into the study. A simple way is through a power prior approach that appropriately weights the prior data by raising its historical likelihood to a power.^[8] Several authors have since extended the power prior approach.^[9,10] Another common approach is to use Bayesian hierarchical modeling. A typical hierarchical model has two levels—a patient level and a study level. In this two-level structure, studies have different but related treatment effects or mean outcomes. That is, the studies are exchangeable or exchangeable conditional on observed covariates.

A key step in the specification of the Bayesian hierarchical model is the selection of the prior for the “between-study” variance. It not only determines the extent of borrowing between studies but also influences the operating characteristics of the design. In an ideal situation, data from several historical studies would be available so that the between-study variance could be given a non-informative prior, and the amount of borrowing among studies would be decided primarily by the data. However, when data from only one historical study are available, the prior for the between-study variance can easily dominate its posterior. In other words, the prior for the between-study variance needs to be informative when utilizing historical data from only one study. The determination of such an informative prior is challenging and in some cases can be done through extensive discussions with clinicians and engineers, while relying on any available published information.

The commensurate prior models have been proposed as alternatives to the customary hierarchical model.^[11] The commensurate prior is a structural prior distribution that describes the extent to which a parameter in this study varies about the analogous parameters in the historical study. The approach assumes that this study borrows strength from the historical study in the absence of evidence for heterogeneity. The authors showed that when properly calibrated within a specific context, this approach could yield good operating characteristics.

The following is a hypothetical example of a medical device clinical trial which shows how historical data are incorporated into the control arm of a study using a Bayesian hierarchical model. We consider a prospective randomized active controlled non-inferiority trial. The investigational device is the 2nd generation of a medical device, while the control device is the 1st generation of the device. The primary endpoint is the proportion of subjects who experience an adverse event at one year. The study success criterion is that the treatment arm is non-inferior to the concurrent control arm if the posterior probability $P\{(p_t - p_c) < \delta | \text{data}\}$ is greater than or equal to 0.95, where p_t and p_c represent the primary event rate at 1 year for the treatment and concurrent control arms, respectively, and δ is the non-inferiority margin. A historical study with n_{hc} patients is available for the control device. Since the historical study and this trial are similar in terms of the targeted patient population, definition and measurement of the clinical endpoints, physician training, etc., a hierarchical model to borrow information from the n_{hc} patients treated with the 1st generation device was considered to augment the control arm. The probability distribution for the number of primary endpoint events in the treatment arm, the concurrent control arm, and the historical control arm is assumed to be binomial: $y_t \sim \text{binomial}(p_t, n_t)$, $y_c \sim \text{binomial}(p_c, n_c)$, $y_{hc} \sim \text{binomial}(p_{hc}, n_{hc})$, respectively. Let

$$\mu_t = \log(p_t / (1 - p_t)),$$

$\mu_c + b_c = \log(p_c / (1 - p_c))$, and $\mu_c + b_{hc} = \log(p_{hc} / (1 - p_{hc}))$. Under the hierarchical model, we assume normal random study effects for the concurrent and historical controls: $b_c \sim N(0, \tau)$ and $b_{hc} \sim N(0, \tau)$. We also assume an improper uniform prior for μ_t and μ_c , and a gamma prior $\Gamma(\alpha, \beta)$ for τ , i.e., $\pi_0(\mu_t, \mu_c, \tau) \propto \tau^{\alpha-1} \exp(-\beta\tau)$ where $\alpha > 0$ and $\beta > 0$. So the joint posterior distribution based on this data $\{y_t, y_c, n_t, n_c\}$ and historical data $\{y_{hc}, n_{hc}\}$ is proportional to the product of prior distribution of μ_c , μ_t , and τ , the likelihood function based on this data $\{y_t, y_c, n_t, n_c\}$, and the likelihood function based on the historical control data $\{y_{hc}, n_{hc}\}$.

To calculate the posterior probability $P\{(p_t - p_c) < \delta | \text{data}\}$ based on the above distribution, sampling via the Gibbs sampler can be performed, and a Monte Carlo estimate of the posterior probability can be obtained. Chen et al.^[9] provide theoretical methodology and a computational

algorithm for the incorporation of historical data via a hierarchical modeling approach.

One should note that type I error cannot be stringently controlled at the customary frequentist level or else no historical data will be borrowed for the control arm.^[12] In this example, the type I error rate tends to be greater if the true event rate in the concurrent control arm is less than the rate observed in the historical control arm. In addition, the values of hyper prior parameters have impact on the strength of borrowing from historical information. Fig. 1 illustrates how type I error rate varies under different hyper priors. H_1 , H_2 , and H_3 represent the hyper prior distributions $\Gamma(\alpha, \beta)$ with different values of α and β [e.g., H_1 , H_2 , and H_3 can be $\Gamma(0.0001, 0.0001)$, $\Gamma(0.001, 0.001)$, and $\Gamma(0.01, 0.01)$, respectively]. The assumed true event rate in the concurrent control arm may occur within the interval from p_0 to p_6 , where $p_0 < p_1 < \dots < p_6$, and p_3 is the observed event rate in the historical control arm. The type I error rate under each hyper prior distribution is calculated through simulation when the true event rate in the concurrent control arm is assumed to be p_0 , or p_1 , or ..., or p_6 . From Fig. 1, we can see that type I error rate is controlled around 0.05 when the concurrent control rate is the same as the observed historical control rate (p_3), and type I error rate increases as the concurrent control rate decreases. The type I error rate curve under hyper prior H_1 has the sharpest slope among three different hyper priors because H_1 allows for more strength of borrowing from historical control than the other two hyper priors.

In order to address a potential concern that the type I error rate might be too high, a conditional borrowing strategy can be considered. If the observed event rate in the concurrent control arm is a prespecified amount lower than the rate from the historical control arm, no historical control data will be borrowed. Deciding the cutoff value for not borrowing historical data will entail communication between the sponsor and the regulatory agency. Since the

Fig. 1 Simulated type I error rate: Sensitivity analysis of robustness of changing hyper prior parameters

Fig. 2 Simulated type I error rate: Sensitivity analysis of robustness of changing hyper prior parameters using conditional borrowing strategy

choice of the hyper prior may impact the type I error rate as well, simulations are needed to calculate the type I error rate for different cutoff values and different hyper priors. Fig. 2 illustrates how type I error rate varies under different hyper priors using the conditional borrowing strategy that if the observed event rate in the concurrent control arm is less than the cutoff p_2 , then no historical control data will be borrowed. From Fig. 2, we can see that type I error rate stops increasing either at the cutoff point p_2 or at a nearby value p_1 . The maximum value of type I error rate under the hyper prior H_3 is controlled at the smallest level among all three hyper priors. Under this approach, the sample size for the new clinical trial is reduced, and the type I error rate is controlled at the agreed upon level under the hyper prior H_3 .

BAYESIAN DESIGN FOR USING ADULT DATA FOR PEDIATRIC INDICATION

The CDRH aims to promote safe and effective device use in pediatric patients, while ensuring device approvals are based on valid scientific evidence. Unfortunately, there is a paucity of scientific evidence available to substantiate submissions for devices that are indicated for use in the diagnosis or treatment of pediatric patients. Leveraging relevant available clinical data from other age groups (perhaps even adults), when appropriate, may lead to more devices being granted marketing authorization for pediatric indications, which will increase the availability of medical devices with appropriate labeling to support safe and effective device use in pediatric patients. The Guidance “Leveraging Existing Clinical Data for Extrapolation to Pediatric Uses of Medical Devices” issued in 2016 was written to explain how leveraging (or “extrapolation”) of adult data might proceed.^[13]

When the use of extrapolation is determined to be appropriate, there are several options for how to extrapolate from adult data. Available options could depend on whether a prospective study of pediatric patients is needed and feasible, and/or whether sufficiently robust pediatric data can be obtained in other ways, such as from prior studies run by the sponsor, studies in the literature, or pediatric registries.

A hierarchical model that statistically combines adult and pediatric studies might be an option if there are multiple adult studies. However, there are likely to be one or more differences that could prevent the assumption of exchangeability between adult and pediatric studies. If these differences can be identified and measured, it is straightforward to account for them in a hierarchical model. When this is done, we can say that the studies are exchangeable, except for measured differences on certain covariates. Often the differences will be related to the size or ongoing growth of the patient. For example, a device whose effect is related to hormone level may have very different magnitudes of effect for adults than for children because they have different circulating hormone levels. If patients are categorized into low, medium, and high hormone levels, then within each category, the adult studies might be exchangeable with the pediatric study. Presumably, if hormone level is highly associated with the effect of the device, a sponsor is likely to have patient-level data on the level of the circulating hormone in adults. Patient-level information in children would enable the sponsor to construct a model that relates hormone level in the blood to the outcome, and thus condition on hormone level to assume exchangeability.

However, differences between adult and pediatric studies could create performance biases in one study but not another, or they could indicate differences in risk that each age group is willing to take. Consequently, the studies might end up with too many differences to assume exchangeability. However, we still want to borrow from the adult studies. In this case, a *three-level* hierarchical model structure may work^[14] and have the consequence of reduced borrowing across adult and pediatric studies in comparison with a two-level hierarchical model. A three-level hierarchical model is easily extended to include covariates. Below, we show an example when normal distributions are used for the outcome y from the i^{th} patient, in the s^{th} study, and p^{th} population.

In Fig. 3, the outcome y has a mean that depends on covariates, $\mathbf{x}$, which can contain a treatment indicator. The study-level regression coefficients in the p^{th} population come from the same multivariate normal distribution $N(\mu_{\beta_p}, \mathbf{R}_p)$. The between-study precision matrices $\mathbf{R}_p$ describe the extent of borrowing among studies within each population and have a prior Wishart distribution with k degrees of freedom. The degrees of freedom must be set to a minimum value (depending on the dimension of β_{sp}) in order for certain moments of the associated inverse-Wishart distribution

Fig. 3 Three-level hierarchical model for borrowing across populations and studies within populations, adjusting for covariates

to exist (see appendix A in Gelman et al.^[1] for details). The between-population precision matrix $\mathbf{R}_0$ describes the extent of borrowing between the two populations. When only one pediatric study is available, however, there is no information about the variation of the $\beta_{s,2}$ coefficients across pediatric studies (i.e., $\mathbf{R}_2$). In most practical device applications, there will not be more than one pediatric study. A simple solution would be to set $\mathbf{R}_1 = \mathbf{R}_2$. Note that the general model in Fig. 3 can be reduced to the usual two-level hierarchical model by setting the between-population precision matrix $\mathbf{R}_0$ to be “infinite.” That is, there is no extra population variability beyond what appears across the studies.

A common situation occurs when the effect of a treatment on a pediatric population is of a lower (or higher) magnitude than on an adult population, due to the pediatric population having a generally lower or higher mean level of a covariate that influences the treatment effect. Kovalchik, Varadhan, and Weiss^[15] discuss a proportional interactions model (PIM), which can be extended to a three-way interaction among treatment, covariate, and population. The covariate interacts with treatment, but the pediatric population has a different covariate mean level than does the adult population. The PIM can be modified so that the regression coefficients vary by study within populations but that proportionality of the treatment by covariate interaction only varies across populations. This modification could apply to any hierarchical model where there is a population level, a study level, and a patient level, along with measured covariates.

Obviously, there may be numerous ways to borrow from adult data, including methods that are not Bayesian. In this section, we have discussed some general approaches to deal with multiple populations and multiple studies. The Guidance “Leveraging Existing Clinical Data for Extrapolation to Pediatric Uses of Medical Devices”^[13] should be consulted for further information and references.

CONCLUSION

Among the most advantageous features of the Bayesian approach for medical device trials are the design and analysis of adaptive trials using predictive distributions and the capability to incorporate prior information into the analysis.

For adaptive trials, predictive probability can be used to determine how to adapt the trial based not only on the available information but also on the predictive distribution for the outcomes to be observed. Such adaptation has been frequently used for sample size modification using intermediate endpoints. The model to relate the intermediate and final endpoints is of paramount importance to the performance of the adaptive design. It should be carefully chosen at the study design stage, preferably based on prior knowledge. Simulation can be used to demonstrate appropriate operating characteristics for adaptive trials.

Bayesian hierarchical modeling enables synthesizing information from various related data sources with appropriate amounts of uncertainty. Such an approach for borrowing information has been used for formal utilization of historical data and for extrapolation of adult data for inference about pediatric use of the same device. The prior for the variance between studies is very influential to the performance of the study design. It should be carefully considered, preferably supported by simulation showing clinically desirable operating characteristics.

The advantages and flexibility in Bayesian methods are reflected in their increasing use in the medical device arena.^[16] In situations where there is prior information that can be used to augment the current trial, or where a flexible adaptive clinical trial is being considered, Bayesian methods often provide the best analytic approach to the problem.

Binary 2×2 Crossover Trials

Li Zhu, Juan Li, and Eric Chi

Amgen Inc., Thousand Oaks, California, U.S.A.

Abstract

This entry reviews the general features of crossover designs and specific features of 2×2 crossover design and discusses in detail four typical tests of this sort.

INTRODUCTION

Crossover design is a commonly used experimental design for the comparison of treatment effects in clinical trials. By letting subject serve as his or her own control, such design automatically removes subject effect from the comparison. Here we focus on the case where the response to each treatment is binary, namely, each subject either succeeded or failed to response to treatment during certain treatment period. Historically, a variety of statistical tests have been developed to serve different purposes. For example, in some crossover trials with the objective of studying the treatments difference, a special test is desired if the response is affected by the order in which the treatments are applied. A thorough review of these tests can enhance our understanding of the methodologies, and hence aid the selection of optimal test in various practical settings.

This article is organized as follows. The general features of crossover designs are briefly reviewed in section “Crossover Design,” followed by an overview of 2×2 crossover design and some typical tests for binary crossover data in section “Tests for 2×2 Crossover Design”; four typical tests are discussed in detail in the following sections “The McNemar Test,” “The Mainland-Gart Test,” “The Prescott Test,” and “The Hills-Armitage Test”; in the end, some concluding remarks on the comparison of the four tests are included in the discussion section.

CROSSOVER DESIGN

As an appealing alternative to parallel designs, crossover designs are commonly applied in today’s pharmaceutical industry. In contrast to parallel designs where each subject receives one single treatment throughout the study, in crossover trials, subjects are given two or more different treatments in some order. Crossover design represents a special situation where there are no separate comparison groups, and each subject serves as his or her own control. Also, because the same subject receives both treatments, there is no possibility of covariate imbalance. One of

the advantages of crossover design is that it eliminates the between-subject variation. Consequently, it requires smaller sample size than parallel design with the same level of significance in testing the treatment effect. Crossover trials are frequently used to compare treatments for medical conditions that are chronic in nature, subject to temporary relief during treatment, and have a tendency to recur after withdrawal of treatment.^[1] They are also commonly used where the between-subject variation is assumed to be large and/or where subjects are scarce or expensive to use.^[2]

A potential problem in crossover design is the *carryover effect*, or *residual effect*, which is the effect that “carries over” from one study period to the subsequent period in which the treatment is changed. Sometimes a wash-out period is set between the treatment periods to minimize any possible carryover effect. But the appropriateness of setting a wash-out period is still in debate for ethical reasons.^[3] In crossover trials, if a *treatment $\times$ period interaction* is present, the differences between treatments as measured in one period may be different from those measured in a later period. Such treatment $\times$ period interaction may result from the true interaction, namely, the conditions present in the different periods truly affect the size of the differences between treatments; nevertheless the treatment $\times$ period interaction may also be a result of treatments possessing different amount of carryover effects. Generally, designs for more than two treatments can be constructed in such a way that they allow the interaction and carryover effect to be estimated separately, however, it is not easy to differentiate the carryover effect from the interaction under the designs of 2×2 crossover for two treatments.^[3] More details will be discussed in the next section.

TESTS FOR 2×2 CROSSOVER DESIGN

The simplest and most commonly used crossover design is the 2×2 crossover design, in which some subjects will receive the standard therapy first, followed by the new therapy (AB), the others will receive the new therapy first,

followed by the standard therapy (BA), and the durations of treatment period are the same for both groups. Some baseline measurements are taken prior to the start of the trial. Then the trial is usually preceded by a run-in period, which is used for screening purposes and to familiarize subjects with the procedures they will follow during the trial. And between the treatment periods, there is usually a wash-out period to allow the effect of the first period treatment to be washed out of the body before the second period in which the treatment is switched. The procedure is illustrated in Fig. 1.

In many situations it is common to have binary outcomes, typically representing success (denoted as 1) or failure (denoted as 0) of a treatment. The data for a 2 × 2 crossover trial can be represented in a 2 × 4 array of counts as shown in Table 1, where n_{ij} 's are the number of subjects in i th sequence treatment group with j th type of paired response.

In the literature, there are specialized testing procedures proposed to test for specific effects, including treatment, period, treatment × period interaction, and group-by-dependence interaction. Also, the different procedures allow the tests to use different types of outcomes. Some typical binary 2 × 2 crossover tests are summarized in Table 2.

Fig. 1 Diagram of 2 × 2 crossover design

Table 1 2 × 2 Crossover Data

	(0,0)	(0,1)	(1,0)	(1,1)	Total
AB	n_{11}	n_{12}	n_{13}	n_{14}	$n_{1.}$
BA	n_{21}	n_{22}	n_{23}	n_{24}	$n_{2.}$
Total	$n_{.1}$	$n_{.2}$	$n_{.3}$	$n_{.4}$	$n_{..}$

Table 2 Some Binary 2 × 2 Crossover Tests

Test name	Effect to test	Outcomes used	Assumptions		
			Period difference	Treatment × Period interaction	Group-by-dependence interaction
McNemar	Treatment	(0,1), (1,0)	×	×	×
Mainland-Gart	Treatment/Period	(0,1), (1,0)	√	×	×
Prescott	Treatment	(0,0), (1,0) (0,1), (1,1)	√	×	×
Hills-Armitage	Treatment × Period Interaction	(0,0), (1,1)	NA	√	NA

The absence of a treatment × period interaction is a critical assumption in most crossover trials. In the absence of such an interaction, the proportion of (1,1) observations among the concordant pairs should be comparable in the two groups. Hills and Armitage^[4] suggest that a test for this interaction by only using non-preference outcomes.

As mentioned in section “Crossover Design,” the treatment × period interaction and carryover effect cannot be disentangled in 2 × 2 crossover trials. This is because there are only three degrees of freedom under the 2 × 2 crossover design; in other words, we can only include three parameters at most without causing unidentifiability. Out of the three parameters, two are associated with the treatment effect and period effect, so only one is left to be associated with the carryover effect and interaction.^[3] Therefore the treatment × period interaction and carryover effect parameters are intrinsically aliased with each other, and cannot be separated except by *a priori* assumption, such as thinking of the carryover as negligible.^[5]

The dependence structure of the paired outcomes is a question of interest in crossover trials, and is tested as *group-by-dependence interaction*, which characterizes how the response is affected by the allocation of treatment sequences to other patients.^[6] Namely, the group-by-dependence interaction measures the difference of treatment × period interaction between the groups.^[2] So if there is no group-by-dependence interaction, the odds ratio of observing a success in the first period as opposed to that in the second period under the AB group should equal to the odds ratio under the BA group.^[7]

THE McNEMAR TEST

McNemar test is a non-parametric method used on nominal data to determine whether the row and column marginal frequencies are equal. It is applied to 2 × 2 contingency tables with a dichotomous trait with matched pairs of subjects (Table 3). Cells represented in the following manner by the letters a , b , c , and d , the totals across rows and columns marginal totals, and the grand total is represented by n .

Table 3 A 2 × 2 Table Used to in the McNemar Test

		Matched case #2		
		1	0	Total
Matched Case #1	1	<i>a</i>	<i>c</i>	<i>a</i> + <i>c</i>
	0	<i>b</i>	<i>d</i>	<i>b</i> + <i>d</i>
	Total	<i>a</i> + <i>b</i>	<i>c</i> + <i>d</i>	<i>n</i>

Table 4 Discordant Pairs of Outcomes from Table 1

	(0,1)	(1,0)	Total
AB	<i>n</i> ₁₂	<i>n</i> ₁₃	<i>n</i> _{1,2+3}
BA	<i>n</i> ₂₂	<i>n</i> ₂₃	<i>n</i> _{2,2+3}
Total	<i>n</i> _{.2}	<i>n</i> _{.3}	<i>n</i> _{..2+3}

Marginal homogeneity implies that the row totals are equal to the corresponding column totals, which means no treatment effect. The null hypothesis can be simplified as $b = c$.

The McNemar statistic Z is a chi-squared statistic with 1 degree of freedom:

$$Z = \frac{(b - c)^2}{b + c} \sim \chi_1^2.$$

In 2 × 2 crossover studies, if the response to each treatment is independent of the order of application, i.e., in the absence of a period effect, the McNemar test^[8] can be used. Only the discordant pairs of the outcomes as shown in Table 4 are used in the McNemar test.

To conduct the McNemar test, the original data is first converted into the structure as in Table 5. Under the null hypothesis of no treatment effect, given that a subject has shown a preference, the choice is equally likely to have been for either treatment. Out of $n_p = n_{.2} + n_{.3}$ subjects who show a preference, a total of $n_A = n_{13} + n_{22}$ of them prefer treatment A, and a total of $n_B = n_{12} + n_{23}$ of them prefer treatment B. Under the null hypothesis, n_A follows a binomial distribution, i.e.,

$$n_A \sim \text{binomial} \left(n_p, \frac{1}{2} \right), \text{ with mean } E(n_A) = \frac{n_p}{2}, \text{ and}$$

$$\text{Var}(n_A) = \frac{n_p}{4}.$$

Hence, $\frac{Z = (n_A - (1/2)n_p)^2}{\text{Var}(n_A)} = \frac{(n_A - n_B)^2}{n_p}$ has an asymptotic χ_1^2 distribution.

For demonstration purpose, we use Mosteller's data^[9] as an example to perform the McNemar test, as well as all the other tests discussed in this article. Table 6 shows the original Mosteller's data.

Here $n_A = 5 + 4 = 9$, $n_B = 0 + 1 = 1$, and $n_p = 4 + 6 = 10$. Because $n_A \sim \text{binomial}(10, 1/2)$, we have $p = 0.0107$ and

Statistic (S)	6.4000
DF	1
Asymptotic Pr > S	0.0114
Exact Pr >= S	0.0215

Fig. 2 SAS code and output for the McNemar test example

doubling this for a two-sided test we get an exact probability of 0.0214. Using the asymptotic method, we compare

$$Z = \frac{(n_A - n_B)^2}{n_p} = \frac{(9 - 1)^2}{10} = 6.4$$

with the χ_1^2 distribution to get a two-sided probability of 0.0114.

The McNemar test can be carried out using SAS frequency procedure. The appropriate SAS code to analyze these data is shown in Fig. 2 with the corresponding output.

Therefore, the results from the McNemar test suggests that the treatment effect is significantly present in this data.

THE MAINLAND-GART TEST

In 2 × 2 crossover trials, each subject receives the two treatments in successive periods, with the order of application being determined randomly. Mainland presents a method of comparing the treatments in the presence of period difference.^[10] Gart^[11] has provided a theoretical interpretation of Mainland's approach in light of a logistic model. This approach was later called the Mainland-Gart test. The data type used in this test is the same as that used in the McNemar test. Namely, the Mainland-Gart test uses only the discordant pairs of the outcomes as illustrated in Table 4.

The theoretical derivation of the test is base on the following logistic models. Let the Bernoulli random variable Y_{ijk} denote the k th subject in the i th treatment group that has the j th type of paired outcome, then we have the logistic models

$$\Pr(Y_{13k_1} = 1) = \frac{e^{\beta_{k_1} + \lambda + \delta}}{1 + e^{\beta_{k_1} + \lambda + \delta}}, \quad \Pr(Y_{22k_2} = 1) = \frac{e^{\beta_{k_2} - \lambda + \delta}}{1 + e^{\beta_{k_2} - \lambda + \delta}},$$

$$\Pr(Y_{12k_1} = 1) = \frac{e^{\beta_{k_1} - \lambda - \delta}}{1 + e^{\beta_{k_1} - \lambda - \delta}}, \quad \Pr(Y_{23k_2} = 1) = \frac{e^{\beta_{k_2} + \lambda - \delta}}{1 + e^{\beta_{k_2} + \lambda - \delta}},$$

Table 5 Data Structure in the McNemar Test

		Prefer B	
		Yes	No
Prefer A	Yes	$n_{.4}$	$n_A = n_{13} + n_{22}$
	No	$n_B = n_{12} + n_{23}$	$n_{.1}$

Table 6 Example: Mosteller's Data

	(0,0)	(0,1)	(1,0)	(1,1)	Total
AB	13	0	5	32	50
BA	17	4	1	28	50
Total	30	4	6	60	100

with $k_1 = 1, \dots, n_{1,2+3}; k_2 = 1, \dots, n_{2,2+3}$. And the parameter λ stands for the period effect, δ is for the treatment effect, and β 's stand for the pair or block effects.

To test the treatment effect, given the total number of successes observed under each treatment, and the total number of subjects in each group, the conditional distribution finally can be derived as hypergeometric (univariate) based on the logistic models aforementioned. Hence the test is equivalent to Fisher's exact test for the usual 2×2 table, i.e., for the test with null hypothesis

$$H_0 : \delta = 0,$$

we have

$$f(n_{13}, n_{22} | n_{13}, n_{23}; \delta = 0, \lambda) = \frac{\binom{n_{1,2+3}}{n_{13}} \binom{n_{2,2+3}}{n_{23}}}{\binom{n_{.,2+3}}{n_{13} + n_{23}}},$$

and the p -value for the one-tailed exact test is

$$P = \frac{\sum_{i=n_{13}}^{n_{1,2+3}} \binom{n_{1,2+3}}{i} \binom{n_{2,2+3}}{n_{13} + n_{23} - i}}{\binom{n_{.,2+3}}{n_{13} + n_{23}}}. \quad (1)$$

On the other hand, we can use the similar idea to test for the period effect. Unlike testing for treatment effect, where the total number of successes observed within each period is fixed, here what is assumed to be fixed is the total number of successes observed under each treatment. Correspondingly, we have

$$H_0 : \lambda = 0,$$

Table 7 Example: Mosteller's Data with Discordant Pairs of Outcomes

	(0,1)	(1,0)	Total
AB	$n_{12} = 0$	$n_{13} = 5$	$n_{1,2+3} = 5$
BA	$n_{22} = 4$	$n_{23} = 1$	$n_{2,2+3} = 5$
Total	$n_{.2} = 4$	$n_{.3} = 6$	$n_{.,2+3} = 10$

$$f(n_{13}, n_{22} | n_{13} + n_{22}; \delta, \lambda = 0) = \frac{\binom{n_{1,2+3}}{n_{13}} \binom{n_{2,2+3}}{n_{22}}}{\binom{n_{.,2+3}}{n_{13} + n_{22}}},$$

$$P = \frac{\sum_{i=n_{13}}^{n_{1,2+3}} \binom{n_{1,2+3}}{i} \binom{n_{2,2+3}}{n_{13} + n_{22} - i}}{\binom{n_{.,2+3}}{n_{13} + n_{22}}}. \quad (2)$$

Furthermore, the treatment effect and period effect can be tested simultaneously:

$$H_0 : \delta = 0, \lambda = 0,$$

by using

$$f(n_{13}, n_{22}; \delta = 0, \lambda = 0) = \binom{n_{1,2+3}}{n_{13}} \binom{n_{2,2+3}}{n_{22}} \left(\frac{1}{2}\right)^{n_{.,2+3}}.$$

If the sample size is large, the joint hypothesis may be tested by

$$\chi^2 = \frac{(2n_{13} - n_{1,2+3})^2}{n_{1,2+3}} + \frac{(2n_{22} - n_{2,2+3})^2}{n_{2,2+3}}.$$

Large values of the test statistic indicates some deviation from the null hypothesis in either or both of the two-sided alternative. For details please see Gart.^[11]

Here we demonstrate an application example by using the Mosteller's data quoted earlier. Table 7 contains only the discordant pairs of outcomes from the full data in Table 6.

From Eq. 1, the one-tailed exact test for treatment effect then yields the p -value:

$$P = \frac{\binom{5}{5} \binom{5}{5+1-5}}{\binom{10}{5+1}} = 0.0238 \quad (3)$$

The result suggests a significant treatment effect. The conclusion is the same as that from McNemar test as shown early. The corresponding SAS code and output are in Fig. 3, and the result is same to that from Eq. 3.

```

/* Mainland-Gart test */

```

Fisher's Exact Test		
Cell (1,1) Frequency (F)		0
Left-sided Pr <= F		0.0238
Right-sided Pr >= F		1.0000
Table Probability (P)		0.0238
Two-sided Pr <= P		0.0476
Sample Size = 10		

Fig. 3 SAS code and output for the Mainland-Gart test example

Similarly, by Eq. 2, the one-tailed exact test for period effect gives the p -value

$$P = \frac{\binom{5}{5} \binom{5}{5+4-5}}{\binom{10}{5+4}} = 0.5 \quad (4)$$

From Eq. 4, it is indicated that the period effect is not significant based on this data.

THE PRESCOTT TEST

An alternative approach was proposed by Prescott to test for differences between treatments in the presence of period effects.^[12] The approach starts to consider the difference $d = x_1 - x_2$, where x_1 and x_2 are the pair of binary outcomes of a subject from the two treatment period. Then d can take the value 1, 0, -1. The simplest method for testing parametrically the null hypothesis of equality of treatment effects is the t -test.^[13] Using data in Table 1, form T as the difference between the responses in the first and second periods

$$T = n_{13} - n_{12},$$

then use this test statistic to compare the mean difference in the AB sequence with the mean difference in the BA

Table 8 Example: Mosteller's Data with Tied Outcomes

	(0,1)	(0,0) or (1,1)	(1,0)	Total
AB	0	45	5	50
BA	4	45	1	50
Total	4	90	6	100

Table 9 All Possible Configurations in the Prescott Test Example

0	45	5	50
4	45	1	50
4	90	6	100
0	44	6	50
4	46	0	50
4	90	6	100
1	43	6	50
3	47	0	50
4	90	6	100

marginal values. So the Prescott test is essentially a permutation t -test. For the one-tailed test against the alternative that treatment A is more effective, given the row and column totals being fixed, we calculate the probability P of observing any configuration with $T > T_0$, where T_0 denotes the observed value of T . Then

$$P = \frac{\sum_{i=T_0}^{n_3} \sum_{j=0}^{\min(i-T_0, n_2)} \binom{n_3}{i} \binom{n_1+n_4}{n_1-i-j} \binom{n_2}{j}}{\binom{n_{..}}{n_{1.}}}$$

We demonstrate the use of the Prescott test by the following example.^[12] The original data in Table 6 with tied outcomes is in Table 8:

For the Prescott test, the test statistic $T = 5 - 0 = 5$. For fixed marginal values, any of the three configurations in Table 9 satisfy $T \geq 5$:

Thus, the p -value for one-tailed test is

$$Pr(T \geq 5) = \frac{\binom{6}{5} \binom{90}{45} \binom{4}{0} + \binom{6}{6} \binom{90}{44} \binom{4}{0} + \binom{6}{6} \binom{90}{43} \binom{4}{1}}{\binom{100}{50}} = 0.0110$$

sequence. To apply the t -test to our binomial situation, this approach suggests to use the same test statistic T , and determine its distribution by considering the values we would obtain for all possible permutations given the fixed

The conclusion is the same as that from both the McNemar and the Mainland-Gart tests.

Using Cytel Studio™ (CrossOver) similar results as shown in Table 10 can be obtained.

Table 10 Results of the Prescott Test for Treatment Effect from Cytel Studio™

Type	One-Sided <i>p</i> -value	Two-Sided <i>p</i> -value
Asymptotic	0.0060	0.0118
Exact	0.0111	0.0222
Mild <i>P</i> Corrected	0.0061	0.0171

Table 11 Results of the Prescott Test for Period Effect from Cytel Studio™

Type	One-Sided <i>p</i> -value	Two-Sided <i>p</i> -value
Asymptotic	0.2577	0.5154
Exact	0.3732	0.7463
Mild <i>P</i> Corrected	0.2687	0.6419

For testing the period effect, results from Cytel Studio™ (CrossOver) are shown in Table 11. Again, they are consistent with the result from the Mainland-Gart test calculated in Eq. 4.

THE HILLS-ARMITAGE TEST

Most of the tests that are commonly used in the 2 × 2 crossover trials are based on the assumption of absence of treatment × period interaction. Such an assumption can be tested by the Hills-Armitage test^[4,13] that uses only the tied outcomes, i.e., the non-preference observations. The non-preference observations as a part of Table 1 are tabulated in Table 12. The test is developed based on the rationale that the effect of an interaction would lead to the difference in the mean response from the two groups A and B, which would be presented by the relative proportions of subjects falling into the categories (0,0) and (1,1). In other words, the frequencies in Table 12 would be disproportionate if a treatment × period interaction exists. This could be tested in the usual way of testing independence in 2 × 2 contingency tables—chi-square test for large sample and exact test for small sample. Examples are given in the following two paragraphs respectively.

Large sample test of independence in contingency tables such as the Pearson chi-square, the continuity-adjusted

Table 12 2 × 2 Table of Non-Preference Observations for the Hills-Armitage Test

	(0,0)	(1,1)	Total
AB	n_{11}	n_{14}	$n_{1,1} + 4$
BA	n_{21}	n_{24}	$n_{2,1} + 4$
Total	$n_{.1}$	$n_{.4}$	$n_{.,1} + 4$

chi-square for 2 × 2 tables, likelihood-ratio chi-square, and the Mantel-Haenszel chi-square are discussed in details in Agresti.^[14] Here we take the usual Pearson chi-square test for example. The Pearson chi-square statistics based on Table 12 can be written as

$$\chi^2 = \sum_{i=1,2} \sum_{j=1,4} \frac{(n_{ij} - \hat{\mu}_{ij})^2}{\hat{\mu}_{ij}}$$

Where $\hat{\mu}_{ij} = \left(\frac{n_{i,1+4}}{n_{.,1+4}} \right) \left(\frac{n_{.j}}{n_{.,1+4}} \right)$. Suppose the non-preference data from Table 9 is actually listed below in Table 13. The chi-square statistics calculated as

$$\chi^2 = \frac{(13-15)^2}{15} + \frac{(32-30)^2}{30} + \frac{(17-15)^2}{15} + \frac{(28-30)^2}{30} = 0.8$$

Given the degree of freedom being 1 for the 2 × 2 table, the corresponding *p*-value is 0.3711.

Small sample test for the 2 × 2 table of non-preference observation can be carried out by Fisher's exact test. The cutoff probability based on Table 12 is calculated using the formula

$$P_c = \frac{\binom{n_{1,1+4}}{n_{11}} \binom{n_{2,1+4}}{n_{21}} \binom{n_{.1}}{n_{11}} \binom{n_{.4}}{n_{21}}}{\binom{n_{.,1+4}}{n_{11}} \binom{n_{.,4}}{n_{21}} \binom{n_{.1}}{n_{11}} \binom{n_{.4}}{n_{21}}}$$

This is the hypergeometric distribution. Taking the same data in Table 13 for example, the cutoff probability is

$$P_c = \frac{(45!)(45!)(30!)(60!)}{(90!)(13!)(32!)(17!)(28!)} = 0.1196$$

In order to get the *p*-value for the exact test, we need to calculate the probability in the same way for each possible 2 × 2 data outcome that gives the same margins as that of the observed data in Table 13. And then add up all the extreme probabilities, namely, the probabilities that are less than the cutoff probability. The summation of extreme probabilities will serve as the *p*-value. When sample size is not very small, statistical software is preferred since the analytical calculation can get tedious.

Since the Hills-Armitage test is essentially the usual test for independence of 2 × 2 tables, it can be simply implemented in the SAS frequency procedure. Using the data in Table 13, both the small sample test and the large sample

Table 13 Example Data of Non-Preference Observations

approximation can be conducted. As shown in Fig. 4, if we use the sample SAS code, we can get the results that are the same as previously calculated.

As shown in the output, both the p -value for the exact test and that for the large sample asymptotic test are larger than 0.05, hence the treatment × period interaction is not present in the data in Table 13.

DISCUSSION

McNemar test, Mainland-Gart test, Prescott test, and Hills-Armitage test are the most commonly used tests in 2 × 2 crossover clinical trials with binary outcomes. Hills-Armitage test focuses on testing treatment × period interaction, and the other three tests focus on testing different effects.

The McNemar test is an extremely simple method, but it has very strong assumptions of no period effect and no carry-over effect. In real-life clinical trials, the assumptions do not always hold. To adjust for period effect, the Mainland-Gart test and the Prescott test are more appropriate.

The Mainland-Gart test is derived from the logistic model, the parameters of individual effects are nuisance and eliminated by having $x_1 + x_2 (=1)$ as fixed for each individual, because only the discordant pairs of the data are used. On the other hand, the Prescott test is a non-parametric test, i.e., it is totally distribution-free. The methods reviewed in the previous sections are appropriate for the small sample cases. The versions of large sample test are also provided in the original paper.^[11,12] In terms of study designs, the Mainland-Gart test does not utilize the information that subjects were allocated at random to the two-treatment sequences, so it is applicable to a wider range of studies than the Prescott test. On the other hand,

the Prescott test is directly based on the randomization that will take place in any well-conducted trial. And it has been shown that under the usual randomization setting, the Prescott test is more powerful than the tests that only use the discordant pair of outcomes, including the McNemar test and the Mainland-Gart test. Therefore, the choice of which test to use should depend on the problem of interest and the specific experimental situation.

The Hills-Armitage test is useful to test potential treatment × period interaction. Since the absence of the treatment × period interaction is the assumption of most tests used in binary crossover trials, it is recommended to always use Hills-Armitage test to check whether treatment × period interaction exists.

Bioassay

Anant M. Kshirsagar

University of Michigan, Ann Arbor, Michigan, U.S.A.

Abstract

The general purpose of a bioassay is to study the potency of a dose from the response it produces. This entry provides statistical methods of performing a bioassay as well as measuring its results.

INTRODUCTION

Finney^[1] defines a bioassay as an experiment for estimating the potency of a drug, material, preparation, or process by means of the reaction that follows its application to living matters. The emphasis in bioassays is on comparing the potencies of treatments rather than estimating the difference between the effects of treatments. For example, Finney points out that an investigation into the effects of different samples of corticotrophin on the ascorbic acid in rat adrenals is not necessarily an assay; it becomes one if the interest lies in using the changes in ascorbic acid for estimating the potencies of the samples in standard units of corticotrophin.

OVERVIEW

The typical bioassay involves a stimulus (for example, a vitamin or a drug) applied to a subject (animal, tissue, or some such experimental unit). The level of the stimulus can be varied and the effect of the stimulus on the subject can be measured in terms of a characteristic we call “response.” The relationship between stimulus and response is a statistical relation subject to a random error. The relationship can be used to study the potency of a dose from the response it produces.

The estimate of potency is always relative to a “standard” preparation of the stimulus. A new test preparation of the stimulus is then assayed to find the mean response to a selected drug. Next we find the dose of the standard preparation that produces the same mean response. The ratio ρ of the dose Z_s of the standard preparation equally effective as this dose Z_M of the test preparation is the relative potency of the test preparation. Thus if $\rho = 4$, 1 unit of the test preparation is as effective as 4 units of the standard preparation.

A statistician must choose a sound design for assaying one or more test preparations. He has to choose the number of levels of doses of each preparation, the number of subjects to be tested at each dose, and the allocation

of the treatments to the units. Sound statistical principles such as randomization, replication, elimination of extraneous sources of variation blocking, and covariates must be employed in designing the experiment for the assay. The data collected are then analyzed and the relative potencies of the test preparation estimated. The statistical techniques that play an important role are analysis of variance and covariance, regression analysis, and linear statistical inference in general. It is necessary to consider carefully the implicit and explicit assumptions about the data and their effect on the conclusions.

There are three types of biological assays: direct assays, indirect assays, and assays based on quantal (“all or nothing”) responses. Direct assays are of fundamental importance. Here the response is measured for a number of doses to establish a statistical dose–response relation, and from this the potency of a test preparation is determined.

PARALLEL-LINE BIOASSAYS

An important type of bioassay is the parallel-line bioassay, in which the dose–response relation is linear for the standard as well as the test preparation and the lines are parallel or that they have a common slope. This linearity can often be achieved by a logarithmic or Box-Cox^[2] type of transformation of the dose and/or the response. The treatments are then applied to the experimental units by using a suitable experimental design, such as randomized blocks, Latin squares, crossover, split-plot, or even an incomplete block design (such as a balanced incomplete block design, partially balanced incomplete block design, or a lattice design). Whether linearity of the dose–response relation is achieved or not, and, if so, whether the slopes of the lines for the standard and test preparations are the same or not, is tested first by what are known as tests of validity, which include the test of parallelism also.

Thus if t_s , t_M denote, respectively, the effects of the standard (S) and the test (M) preparation, the parallel lines representing the dose–response relation can be taken as

$$t_s = \alpha_s + \beta x_s$$

$$t_M = \alpha_M + \beta x_M$$

where x_s, x_M are, respectively, $\log Z_s$ and $\log Z_M$, and Z_s, Z_M are the doses of s and M in original units. If ρ is the relative potency of M with respect to s , then ρZ_M and Z_s produce the same effect, and this leads to

$$\log \rho = \frac{\alpha_M - \alpha_s}{\beta}$$

This can be expressed in terms of the treatment contrasts, using

$$\alpha_M - \alpha_s = \bar{t}_M - \bar{t}_s - \beta(\bar{x}_M - \bar{x}_s)$$

$$\beta = \frac{\sum t_M (x_M - \bar{x}_M) + \sum t_s (x_s - \bar{x}_s)}{\sum (x_M - \bar{x}_M)^2 + \sum (x_s - \bar{x}_s)^2}$$

where $\bar{t}_M, \bar{t}_s$ etc. are the averages and the summation is over the doses of S and M . The contrast $\alpha_M - \alpha_s$ is called the *preparation contrast*; the contrast β is called the *regression contrast*. The contrasts can be estimated from the observations in the experimental design. In complete block designs, these estimates are obtained simply by replacing the treatment effects by their average yields; in incomplete block designs, however, one needs to use adjusted treatment yields for this response, after confirming that the contrasts are estimable. In fact, designs should be chosen so that these two contrasts are unconfounded and are estimated with maximum precision. Mukerjee and Gupta^[3] have studied efficient designs for this purpose and have attempted to unify the results in this area. Finney^[1] and Das and Kulkarni^[4] give several examples of complex and incomplete block designs to be used in parallel-line bioassays. The validity tests are based on orthogonal polynomial contrasts of the treatment effects, such as

$$\sum P_{Sr} t_s \text{ and } \sum P_{Mr} t_s$$

where P_{Sr}, P_{Mr} are orthogonal polynomials of the r th degree in the values of the doses of S and M . In a well-planned experiment, the doses are chosen to be equal in number and also equidistant on a log scale so that tables of orthogonal polynomial can be used to construct these contrasts. If reduction in block size is inevitable, one has to resort to confounding of validity contrasts of higher degrees. Kshirsagar and Yuan^[5] have developed a unified theory of parallel-line bioassays in incomplete block designs. Wang and Kshirsagar^[6] give an illustration of the use of lattice squares—a two-way design with incomplete rows and columns, to estimate the relative potency of several preparations. Recovery of interblock or interrow and intercolumn information can also be

utilized in increasing the precision of the estimates of the preparation and regression contrasts if the blocks (i.e., rows and columns) are chosen at random. A confidence interval for ρ can then be obtained by using Fieller's method^[7] for the ratio of the two contrasts in defining $\log \rho$. The assumption of normal distribution and homogeneity of variances of errors is necessary for carrying out this analysis.

If the linearizing transformation of dose is not logarithmic but of the type $X = Z^\lambda$, the relative potency turns out to be $\rho = (\beta_M/\beta_s)^{1/\lambda}$, provided the dose-response lines of S and M intersect and have slope β_M, β_s for M and S , respectively, and provided the intercepts of α_M, α_s of the two lines are equal. The validity of these assumptions in such slope-ratio assays will have to be tested by testing the departure from linearity of the dose-response regression lines and a test of significance of $\alpha_M - \alpha_s$. It is expected that when $x_s = x_M = 0$, the response should be the same for S and M , and this is tested by introducing "blanks" (neither S nor M) in the experiment.

Völund^[8] has discussed bioassays in the case of multivariate responses. In the case of multiple responses and multiple doses (in which the test or standard preparation is made up of several component drugs or chemicals), composite functions such as discriminant functions or canonical variables could be used, as discussed by Finney^[1] and by Yuan and Kshirsagar.^[9,10]

QUANTAL RESPONSE AND THE TOLERANCE DISTRIBUTION

Sometimes, it is not possible to measure the response and all that can be done is to record whether or not the subject manifests a certain reaction. The response in such cases is quantal, and can be death or any other easily recognizable change in the subjects. Such a change could be irreversible, and a subject can, therefore, be used only once. Such a situation arises in the assaying of insecticides, fungicides, or pesticides or assays of insulin or estrogenic hormones or assays of vitamins. The tolerance of a subject is then defined as the minimum dose that would produce the desired effect. In a direct assay, the tolerance is measured for each subject and the potency is estimated by comparing mean tolerance. In a quantal assay, a selected dose is used, and one can only record whether or not the change occurred and infer from that whether the tolerance was greater or less than the dose used. The potency in quantal assays is estimated by use of the relation between the dose and the proportion of subjects responding. This proportion does not necessarily have a linear regression on dose or its transform. It is customary to assume a suitable distribution for tolerance or log tolerance for approximate linearization. The potency is sometimes characterized by the median lethal dose or, more generally, the median effective dose, symbolized, respectively, by LD50 and ED50. This is a dose that, on an average, produces the desired response in 50% of the subjects. For estimating ED50, the parameters of the tolerance

distribution are estimated first from the data, by using the maximum likelihood estimation method or the minimum χ^2 method or some such suitable method. The assumption of a normal distribution for tolerance leads to what is known as *probit analysis* and the assumption of a logistic distribution leads to *logit analysis*. If $f(z)$ is the probability density function of the tolerance distribution, the probability p that the tolerance of a subject is less than x is

$$p = \int_{-\infty}^x f(z) dz = \int_{-\infty}^y \phi(z) dz$$

where $y = (x - \mu)/\sigma$, μ , σ^2 being, respectively, the mean and variance of the normal distribution of Z and $\phi(z)$ is the p.d.f. of a standard normal variable. If the distribution function of a standard normal distribution is denoted by Φ and its inverse by Φ^{-1} , we then have

$$\Phi^{-1}(p) = \alpha + \beta x$$

where α , β are transforms of μ and σ . One can then estimate ED50 or LD50 by the probit method. The method of scoring^[11] is generally used to solve the maximum-likelihood equations. Several tolerance distributions, such as normal, logistic, binomial, Wilson-Worcester, and angle sigmoid, have been discussed and employed in the literature, and one may refer to Finney,^[1] Govindrajulu,^[12] or Hubert^[13] for further details. The iterative calculations needed to solve the maximum-likelihood equations are laborious, and alternative, simpler but approximate, methods were developed earlier. These include the Spearman-Kärbes, Dragstedt-Behrens, and Reed-Muench.^[1] However, they have lost their merit due to the availability of ready-made computer programs.

Finney^[1] has discussed the principles of planning an assay. He stresses the importance of validity or consistency of an estimate of the relative potency, the economics of the assay design, the necessity of pilot investigations before choosing an optimum design, the simplicity of a symmetric design, and the cost of statistical analysis. He has given specific detailed recommendations for parallel-line and slope ratio assays as well as quantal assays.

For some assays, the measured response is time: usually the time that elapses between the application of the stimulus and the occurrence of some reaction. In such time-response assays the main difficulty is that the assay may end before a response has been measured for every subject. Finney^[1] suggests converting the data to a quantal focus or assigning an arbitrary value as the response for subjects that have not reacted when the assay ends or using a mathematical model for reaction time in such cases.

The relative potency of a test preparation may also change with time due to storage or environmental conditions and the dependence on time of the relative potency can be studied using a growth-curve type of model for the preparation and slope contrast, as in Bandekar and Kshirsagar,^[14] for example. Multivariate bioassays have been discussed by Carter

and Huber,^[15] Williams,^[16] Hui and Rosenberg,^[17] Vølund,^[8] Meisner et al.,^[18] and Srivastava.^[19] For the Bayesian analysis of parallel-line and slope-ratio bioassays, reference may be made to Darley^[20] and Meudoza.^[21] Distribution-free methods for the estimation of relative potency have been discussed by Sen^[22] and Bennett.^[23]

Bioavailability and Bioequivalence

Mengdie Yuan and Jingyu Julia Luan

Center for Drug Evaluation and Research, Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

Bioavailability/Bioequivalence (BA/BE) studies are often conducted in support of marketing applications for drugs and biologics. The Hatch-Waxman Act particularly enhanced the generic drug marketing and the evolution of BE studies after 1984. The Code of Federal Regulations lists pharmacokinetic (PK) study, pharmacodynamic (PD) study, clinical endpoint study, and in vitro study as methods for determining BA/BE. In PK studies, three approaches are used to demonstrate BE: average BE, population BE, and individual BE. With the development of generic products for highly variable drugs and narrow therapeutic index drugs, reference-scaled BE approaches are employed. For certain types of drugs, clinical endpoint studies may be the most appropriate way to demonstrate BE, for which the approaches to demonstrating BE are also well developed.

Keywords: Average bioequivalence; Comparative clinical endpoint study; Comparative PK study; Generic drugs; Highly variable drugs; Individual bioequivalence; Narrow therapeutic index drugs; Population bioequivalence.

INTRODUCTION

The US Code of Federal Regulations 21 CFR 320^[1] describes the bioavailability (BA) and bioequivalence (BE) requirements of the US Food and Drug Administration (FDA). It defines BA as “the rate and extent to which the active ingredient or active moiety is absorbed from a drug product and becomes available at the site of action” and BE as “the absence of a significant difference in the rate and extent to which the active ingredient or active moiety in pharmaceutical equivalents or pharmaceutical alternatives becomes available at the site of drug action when administered at the same molar dose under similar conditions in an appropriately designed study.” BA/BE studies are often conducted in support of US marketing applications including Investigational New Drug Applications (INDs), New Drug Applications (NDAs), Biologics Licensing Applications (BLAs), and Abbreviated New Drug Applications (ANDAs). BA studies aim to assess the in vivo pharmacokinetic (PK) performance for drug absorption, distribution, and elimination for a new molecular entity, while BE studies aim to compare the BA of various formulations with regard to the rate and extent of absorption. BE studies occur in both the generic drug development and the new drug development with formulation or strength change. In generic drug development, demonstrating BE became key to allaying concerns that the generic was not as bioavailable as the reference drug.^[2] The Hatch-Waxman Act (1984) established the modern system of generic drugs, authorizing the FDA to approve generic drugs under an

abbreviated process that did not require repetition of the research done by the innovator that established safety and efficacy, enhancing the development of generic drugs and the evolution of BE studies. BE studies are essential in the evaluation of therapeutic equivalence between the test drug product and the reference drug product. Indeed, the two products are considered as therapeutically equivalent, which means that the test product and the reference product are expected to have the same safety and efficacy, if they meet the regulatory criteria of pharmaceutical equivalence and BE. Under 21 CFR 320.24,^[1] the FDA may accept evidence from various approaches to determine BA or BE, including the following:

1. An in vivo test (PK study) in humans in which the concentration of the active ingredient or active moiety, and, when appropriate, its active metabolite(s), in whole blood, plasma, serum, or other appropriate biological fluid are measured as a function of time, or an in vitro test that has been correlated with and is predictive of human in vivo BA data
2. An in vivo test in humans in which the urinary excretion of the active moiety, and, when appropriate, its active metabolite(s), are measured as a function of time
3. An in vivo test (pharmacodynamics [PD] study) in humans in which an appropriate acute pharmacological effect of the active moiety, and, when appropriate, its active metabolite(s), are measured as a function of time if such effect can be measured with sufficient accuracy, sensitivity, and reproducibility

4. Well-controlled clinical trials that establish the safety and effectiveness of the drug product, for the purpose of measuring BA, or appropriately designed comparative clinical trials, for the purpose of demonstrating BE
5. A currently available in vitro test acceptable to FDA that ensures human in vivo BA
6. Any other approach deemed adequate by FDA to measure BA or establish BE

The methods are listed in descending order of accuracy, sensitivity, and reproducibility. Method 1 is particularly applicable to dosage forms intended to deliver the active moiety to the bloodstream. Method 2 is not appropriate where urinary excretion is not the main mechanism of elimination. Method 3 is used when Methods 1 and 2 are not applicable and a method is available for measurement of the acute pharmacological effect. Method 4 is the least accurate, sensitive, and reproducible of the general approaches for measuring BA or demonstrating BE; it is acceptable only when the aforementioned methods cannot be developed and may be considered sufficient when BA/BE is to be determined for dosage forms intended to deliver the active moiety locally, oral dosage forms not intended to be absorbed, or bronchodilators administered by inhalation if the onset and duration of pharmacological activity are defined.^[1]

In general, plasma PK studies provide useful information in assessing BA and demonstrating BE. For locally acting products such as topical dermatological products or those nasal sprays and inhalation products that are intended for local action, traditional plasma PK studies can be useful to evaluate systemic exposure and safety but may not necessarily be relevant for evaluating BE because the drug levels in the systemic circulation may not necessarily be representative of local BA of the drug at or near the site of action. In some situations, comparative clinical endpoint studies have been used to determine BE.^[3] Shah et al. specifically introduced the methods to assess the BA/BE for topical drugs and discussed the challenges.^[4] In this article, we will focus on discussing the study designs and statistical approaches to demonstrating BE in comparative PK studies and comparative clinical endpoint studies.

PK BE STUDY

Study Design

PK BE studies aim to compare the systemic exposure profile of a test drug product (*T*) to that of a reference drug product (*R*). A standard PK BE study design is based on the administration of either single or multiple doses of *T* and *R* to healthy subjects with random assignment to two possible sequences of drug product administration. FDA recommends performing BE studies as single-dose PK

studies for both immediate-release and modified-release drug products because such studies are generally sensitive in assessing the release of the drug substance from the drug product into the systemic circulation.^[5] Useful multiple-dose studies have also been discussed in 21 CFR 320.27.^[1] El-Tahtawy et al. compared single-dose and multiple-dose studies in BE assessment.^[6] Also, clearance, volume of distribution, and absorption in the study are assumed to have less inter-occasion variability compared to the formulation variability so that differences contributed by formulation can be determined.^[5] Generally, non-replicated crossover study designs are recommended for BE studies. However, replicated crossover study designs have the advantage of accounting for the within-subject variability when comparing *T* and *R*, and also the advantage of reducing the number of subjects. In particular, they allow the use of methods based on within-subject variability to assess the BE such as reference-scaled approaches for highly variable (HV) drugs and narrow therapeutic index drugs, as discussed below. Examples of commonly used nonreplicated crossover study design and replicated crossover study designs are shown in Tables 1 and 2. Usually, consecutive periods are separated by an adequate washout period to eliminate the carryover effect. In situations where carryover effects are present, higher order crossover design is recommended.^[7] In some situations such as when the drug has a long half-life, a parallel design may be more appropriate due to the likelihood of dropouts during the required long washout period.^[2] For discussions on more types of BE study design, the interested reader can refer to Chapter 3.4 in Yu and Li.^[2] In addition, the study should enroll enough subjects to sufficiently power the study. Phillips provided a table of sample sizes based on Schuirmann's^[15] two one-sided tests (TOSTs).^[8] Later Liu and Chow provided the approximate formulas for calculation of the sample sizes.^[9]

Table 1 Nonreplicated Design

		Period	
		1	2
Two-period two-sequence crossover			
Sequence	1	<i>T</i>	<i>R</i>
	2	<i>R</i>	<i>T</i>

Table 2 Replicated Design

		Period			
		1	2	3	
Three-way crossover					
Sequence	1	T	R	T	
	2	R	T	R	
		Period			
Four-way crossover		1	2	3	4
Sequence	1	T	R	T	R
	2	R	T	R	T

PK Measures

In BA/BE studies, the blood or plasma concentration is measured after drug administration. Typically, 12–18 samples at various time points will be collected per subject per dose. The concentration–time curve is adopted to profile the drug absorption. As discussed, BE studies aim to compare the BA of various formulations with regard to the rate and extent of absorption. Instead of directly comparing the measures of absorption such as rate constant, rate profile, mean absorption time, mean residence time, peak drug concentration (C_{max}), and time to achieve peak concentration (T_{max}), we normally compare the measures of systemic exposure such as peak drug concentration (C_{max}) area under the curve (AUC). In particular, partial AUC ($pAUC$) truncated at the population median of T_{max} of the reference product can measure the early exposure to the drug; C_{max} can directly measure the peak exposure to the drug; and AUC from time 0 to the last sample point (AUC_{0-t}) or AUC from time 0 to infinity can measure the total exposure ($AUC_{0-\infty} = AUC_{0-t} + C_t/\lambda_z$), where C_t is the concentration at the last sample point and λ_z is a calculated terminal rate constant. The choice of the PK measures for comparison depends on the dosage forms and should be able to capture the relevant differences in the PK profile. The measures of peak exposure and total exposure are commonly used to demonstrate BE. The measures of early exposure are useful where a better control of the drug absorption is essential for drug efficacy and safety.^[10–12] Usually, C_{max} and AUC are informative for immediate-release and modified-release dosage forms, but are not always sufficient for some modified-release dosage forms that exhibit multiphasic PK behavior where the use of $pAUC$ may be appropriate.^[2] Moreover, AUC over a dosing interval at steady state is an appropriate measure of total exposure for steady-state studies.

Statistical Approaches for BE Assessment

BE comparisons are based on an equivalence approach that specifies a function of parameters for testing and a decision criterion to establish BE. In addition, a logarithmic transformation of the PK measures is applied before statistical analysis. Initially, a variety of statistical methods were used to assess BE.^[13] Later, statistical approaches based on hypothesis testing were developed and are employed to this day.^[2] Specifically, the hypotheses of interest can be written as

$$H_0 : \Theta > \theta \text{ versus } H_A : \Theta \leq \theta,$$

where Θ is a function of parameters for comparison between T and R , and θ is the BE margin. BE is assessed by testing the hypotheses at a desired level of significance, say

5%; by rejecting the null hypothesis H_0 , one can conclude the BE between T and R . We conduct the hypothesis testing based on a linear mixed-effects model. Suppose μ_T and μ_R are the logarithmic population mean of the PK measure of interest (e.g., C_{max} , AUC) for T and R , σ_{BT}^2 and σ_{BR}^2 are the between-subject variances of that measure for T and R , and σ_{WT}^2 and σ_{WR}^2 are the within-subject variances for T and R , respectively. The total variances are $\sigma_{TT}^2 = \sigma_{BT}^2 + \sigma_{WT}^2$ and $\sigma_{TR}^2 = \sigma_{BR}^2 + \sigma_{WR}^2$ for T and R , respectively. We allow a constant within-subject correlation between T and R denoted as ρ . The variance component of subject-by-formulation interaction can then be written as

$$\sigma_D^2 = (\sigma_{BT} - \sigma_{BR})^2 + 2(1 - \rho)\sigma_{BT}\sigma_{BR}.$$

In the situation where a small subgroup of the general population have markedly different relative BA of T and R from the general population, or T and R are not bioequivalent for this subgroup but might be bioequivalent for the general population, a subject-by-formulation interaction should be considered.

Currently, there are three approaches to demonstrating BE described in FDA Guidance: average BE (ABE), population BE (PBE), and individual BE (IBE).^[14] Note that ABE is the most frequently used approach. Next, we will introduce these three approaches and their properties.

Average BE

For ABE, we are interested in $\Theta_A = (\mu_T - \mu_R)^2$. Then the hypotheses for testing ABE are

$$H_0 : (\mu_T - \mu_R)^2 > \theta_A^2 \text{ versus } H_A : (\mu_T - \mu_R)^2 \leq \theta_A^2,$$

where θ_A is the ABE margin. FDA currently recommends $\theta_A = \ln(1.25)$.

Schuirman^[15] proposed to conduct TOSTs as follows:

$$H_0 : \mu_T - \mu_R < -\theta_A \quad \text{vs.} \quad H_A : \mu_T - \mu_R \geq -\theta_A$$

and

$$H_0 : \mu_T - \mu_R > \theta_A \quad \text{vs.} \quad H_A : \mu_T - \mu_R \leq \theta_A,$$

where θ_A is the BE margin. Therefore, ABE compares the logarithmic population mean of the PK measure. Note that it is equivalent to conducting hypothesis testing on the geometric mean ratio (GMR) which is the exponential of the difference in the logarithmic mean. Based on TOST, we construct a 90% confidence interval (CI) for estimated $\mu_T - \mu_R$. If the 90% CI is contained within $[-\theta_A, \theta_A]$, then BE is established. The rationale for the choice of the significance level (90%) and the margin (80%–125%) has been intensively discussed in the literature.^[2,16–19]

Population BE

The FDA^[14] recommends the following reference-scaled approach for testing PBE:

When $\sigma_{TR} > \sigma_{T0}$, use

$$\begin{aligned} H_0 : \frac{(\mu_T - \mu_R)^2 + \sigma_{TT}^2 - \sigma_{TR}^2}{\sigma_{TR}^2} > \theta_p \text{ versus} \\ H_A : \frac{(\mu_T - \mu_R)^2 + \sigma_{TT}^2 - \sigma_{TR}^2}{\sigma_{TR}^2} \leq \theta_p, \end{aligned} \quad (1)$$

and when $\sigma_{TR} \leq \sigma_{T0}$, use

$$\begin{aligned} H_0 : \frac{(\mu_T - \mu_R)^2 + \sigma_{TT}^2 - \sigma_{TR}^2}{\sigma_{T0}^2} > \theta_p \text{ versus} \\ H_A : \frac{(\mu_T - \mu_R)^2 + \sigma_{TT}^2 - \sigma_{TR}^2}{\sigma_{T0}^2} \leq \theta_p, \end{aligned}$$

where σ_{T0}^2 is a specified constant for the total variance and θ_p is the PBE margin. The determination of σ_{T0}^2 is based on the maximum allowable population difference ratio (PDR) and $\sigma_{TT}^2 - \sigma_{TR}^2$. Note that the true σ_{TT}^2 is unknown and cannot be observed in studies. Therefore, in practice, we usually compare the observed total standard deviation with a prespecified cutoff point. The choice of the margin θ_p should consider both the ABE and the variance term in PBE. The FDA recommended a PBE margin as

$$\theta_p = \frac{\theta_A^2 + \varepsilon_p}{\sigma_{T0}^2},$$

where ε_p is a variance factor, the value of which is guided by $\sigma_{TT}^2 - \sigma_{TR}^2$. We can construct the 95% upper confidence limit (UCL) for estimated $(\mu_T - \mu_R)^2 + \sigma_{TT}^2 - \sigma_{TR}^2 - \theta_p \sigma_{TR}^2$ or $(\mu_T - \mu_R)^2 + \sigma_{TT}^2 - \sigma_{TR}^2 - \theta_p \sigma_{T0}^2$ depending on the observed total standard deviation for R and compare the 95% UCL with zero. If the 95% UCL is less than or equal to zero, the PBE is established. Note that the interest of PBE lies in the comparison of the PDR, which can be expressed as

$$\begin{aligned} \frac{E(T - R)^2}{E(R' - R)^2} &= \frac{(\mu_T - \mu_R)^2 + \sigma_{TT}^2 + \sigma_{TR}^2}{2\sigma_{TR}^2} \\ &= \frac{1}{2} \times \frac{(\mu_T - \mu_R)^2 + \sigma_{TT}^2 - \sigma_{TR}^2}{\sigma_{TR}^2} + 1 \\ &= \frac{1}{2} \Theta_p + 1, \end{aligned}$$

where $\Theta_p = \frac{(\mu_T - \mu_R)^2 + \sigma_{TT}^2 - \sigma_{TR}^2}{\sigma_{TR}^2}$ is the function of parameters in Hypotheses (1).

PBE is relevant in the context of drug interchangeability when either T or R was prescribed to subjects for the first

time since PBE makes sure that not only the population mean but also the population variability is similar between T and R .^[2] Note that this approach shows discontinuity at the changeover point σ_{T0} . The 95% UCL will jump high at the changeover point as the observed standard deviation for R becomes larger. Also, this approach inflates the type I error rate slightly for a range of scenarios.^[14]

Individual BE

For IBE, we can also use a similar approach as PBE but with the interest lying in the comparison of the individual difference ratios (IDRs) by considering the within-subject variance instead of the total variance. That is,

When $\sigma_{WR} > \sigma_{W0}$, use

$$\begin{aligned} H_0 : \frac{(\mu_T - \mu_R)^2 + \sigma_{WT}^2 - \sigma_{WR}^2 + \sigma_D^2}{\sigma_{WR}^2} > \theta_I \text{ vs.} \\ H_A : \frac{(\mu_T - \mu_R)^2 + \sigma_{WT}^2 - \sigma_{WR}^2 + \sigma_D^2}{\sigma_{WR}^2} \leq \theta_I, \end{aligned} \quad (2)$$

and when $\sigma_{WR} \leq \sigma_{W0}$, use

$$\begin{aligned} H_0 : \frac{(\mu_T - \mu_R)^2 + \sigma_{WT}^2 - \sigma_{WR}^2 + \sigma_D^2}{\sigma_{W0}^2} > \theta_I \text{ vs.} \\ H_A : \frac{(\mu_T - \mu_R)^2 + \sigma_{WT}^2 - \sigma_{WR}^2 + \sigma_D^2}{\sigma_{W0}^2} \leq \theta_I, \end{aligned}$$

where σ_{W0}^2 is a specified constant for the within-subject variance and θ_I is the IBE margin. Similarly, the determination of σ_{W0}^2 is based on the maximum allowable IDR, $\sigma_{WT}^2 - \sigma_{WR}^2$, and σ_D^2 . The value of the θ_I can be chosen as

$$\theta_I = \frac{\theta_A^2 + \varepsilon_I}{\sigma_{W0}^2},$$

where ε_I is a variance factor, the value of which is guided by $\sigma_{WT}^2 - \sigma_{WR}^2 + \sigma_D^2$. The FDA recommends allowing 0.03 for $\sigma_{WT}^2 - \sigma_{WR}^2$ and 0.02 for σ_D^2 , i.e., 0.05 for ε_I .^[14] We can construct the 95% UCL for estimated $(\mu_T - \mu_R)^2 + \sigma_{WT}^2 - \sigma_{WR}^2 + \sigma_D^2 - \theta_I \sigma_{WR}^2$ or $(\mu_T - \mu_R)^2 + \sigma_{WT}^2 - \sigma_{WR}^2 + \sigma_D^2 - \theta_I \sigma_{W0}^2$ depending on the observed within-subject standard deviation for R and compare the UCL with zero. If the 95% UCL is less than or equal to zero, then IBE is established. Similarly, we can show that

IDR is a function of $\Theta_I = \frac{(\mu_T - \mu_R)^2 + \sigma_{WT}^2 - \sigma_{WR}^2 + \sigma_D^2}{\sigma_{WR}^2}$ in

Hypotheses (2).

IBE is useful in the context of drug switchability for a subject who has been taking the test product or the reference product to switch to the other one without compromising the safety or efficacy.^[2]

For feasible models and methods for constructing the 95% UCL for ABE, PBE, and IBE, refer to FDA Guidance.^[14]

Highly Variable Drugs

Drugs with within-subject % coefficient of variation (%CV) greater than 30% for at least one PK measure are considered as highly variable (HV) drugs. A survey of generic products from 2003 to 2005 has suggested that approximately 20% of generic drugs should be considered as HV due to their drug substance dispositional characteristics.^[20] HV drugs tend to have a wider 90% CI compared to normal drugs even with the same mean ratio, and therefore are less likely to pass the BE test. It may turn out that a dramatically large sample size is needed to meet the BE criterion. Given this concern, the FDA's Office of Generic Drugs raised the issue in an Advisory Committee Meeting in 2004, where a reference-scaled approach was recommended. Later, this approach was further investigated and finalized with simulation studies,^[21] and is referred to as reference-scaled average BE (RSABE). Note that the BE study should be a replicated study in order to use the RSABE approach. The RSABE approach for HV drugs is modified from the ABE approach and described next.

When $\sigma_{WR} > \sigma_{W0}$, use

$$H_0: \frac{(\mu_T - \mu_R)^2}{\sigma_{WR}^2} > \frac{\theta_A^2}{\sigma_{WR}^2} \quad \text{vs.} \quad H_A: \frac{(\mu_T - \mu_R)^2}{\sigma_{WR}^2} \leq \frac{\theta_A^2}{\sigma_{WR}^2},$$

and when $\sigma_{WR} \leq \sigma_{W0}$, use

$$H_0: \frac{(\mu_T - \mu_R)^2}{\sigma_{W0}^2} > \frac{\theta_A^2}{\sigma_{W0}^2} \quad \text{versus} \quad H_A: \frac{(\mu_T - \mu_R)^2}{\sigma_{W0}^2} \leq \frac{\theta_A^2}{\sigma_{W0}^2},$$

where σ_{W0}^2 is a specified constant for the within-subject variance and $\theta_A = \ln(1.25)$ is the ABE margin. The FDA proposed the use of cutoff point of $\sigma_{W0} = 0.294$ in the draft guidance on progesterone.^[22] In that guidance, the FDA describes a procedure for BE testing and provides an example of SAS codes to elaborate the RSABE approach. However, the RSABE approach may allow a product to pass the BE test even with the point estimate of the GMR outside [0.8, 1.25]. Therefore, the FDA^[23] recommends imposing a further constraint that the point estimate of the GMR should be contained within [0.8, 1.25]. The constraint is controversial especially when the within-subject %CV exceeds 50%–60% because the BE test will be dominated by the constraint, resulting in the need for an increased sample size to demonstrate BE.

However, the constraint is still adopted by regulatory agencies such as the FDA, European Medicines Agency (EMA), and Australian Therapeutic Goods Administration.^[2]

Narrow Therapeutic Index Drugs

For narrow therapeutic index (NTI) drugs, a small change in the blood concentration can potentially cause therapeutic failure or serious adverse events in the subject. The Code of Federal Regulations 21 CFR 320.33^[1] provides possible definitions of narrow therapeutic index: (1) there is less than a twofold difference in median lethal dose (LD50) and median effective dose (ED50) values, and (2) there is less than a twofold difference in the minimum toxic concentrations and minimum effective concentrations in the blood. There exist numerous reports raising concerns of the BE approaches for certain generic products, for example, levothyroxine, and the switchability of the generic product for the reference product. In particular, 13 US states have considered a list of specific NTI drugs nonsubstitutable.^[2] Therefore, more stringent BE approaches are needed. After careful consideration,^[24,25] the FDA recommends a four-way replicated crossover design to demonstrate BE for NTI drugs and an RSABE approach on mean comparison plus a within-subject variability comparison for BE testing^[2] (see, e.g., the draft guidance on warfarin sodium^[23]).

Mean Comparison

The hypotheses are

$$H_0: \frac{(\mu_T - \mu_R)^2}{\sigma_{WR}^2} > \theta \quad \text{versus} \quad H_A: \frac{(\mu_T - \mu_R)^2}{\sigma_{WR}^2} \leq \theta,$$

where θ is a reference-scaled BE limit. The FDA recommends the use of $\theta = \ln(1/0.9)^2 / \sigma_{W0}^2$ and $\sigma_{W0} = 0.1$ for warfarin sodium.^[23] For different products, θ could be different. Furthermore, the FDA recommends that the NTI drugs also pass the ABE in support of approval.^[2]

Within-Subject Variability Comparison

In addition to the mean comparison, we also need to test the following hypotheses for within-subject variability:

$$H_0: \frac{\sigma_{WT}}{\sigma_{WR}} > \delta \quad \text{vs.} \quad H_A: \frac{\sigma_{WT}}{\sigma_{WR}} \leq \delta,$$

where δ is a limit to control the test variability to be no more than the reference variability. The FDA proposed $\delta = 2.5$ for warfarin sodium.^[23]

In the guidance,^[23] the FDA also describes a procedure for conducting the two above comparisons and provides an example of SAS codes to elaborate the approach. Other agencies such as Health Canada and EMA have considered directly tightening the ABE limits, say [90.00%, 111.11%], for NTI drugs.^[2]

CLINICAL ENDPOINT BE STUDY

Study Design

As discussed earlier, for dosage forms intended to deliver the active moiety locally, oral dosage forms not intended to be absorbed, or bronchodilators administered by inhalation if the onset and duration of pharmacological activity are defined, plasma PK studies may not be relevant to evaluate BE.^[1] Instead, clinical endpoint studies can be used. Generally, clinical endpoint BE studies are randomized, double-blind, placebo-controlled three-arm, parallel groups designed to compare two formulations. The placebo arm is usually but not necessarily included in the clinical endpoint BE studies to evaluate if the study is sufficiently sensitive to detect the clinical effect in the study population. Patients intended to treat are enrolled in the clinical endpoint BE studies, while PK BE studies are conducted on healthy volunteers. Note that the number of subjects enrolled in clinical endpoint BE studies can be much smaller than that in the registration clinical trials in new drug development. Unlike demonstrating efficacy with the registration clinical trials of new drugs, clinical endpoint BE studies are a less sensitive, accurate, and reproducible approach to demonstrating BE compared to other approaches such as PK BE studies. Also, compared to other approaches to demonstrating BE, clinical endpoint BE studies are expensive and time consuming.^[2] However, under some circumstances, clinical endpoint BE studies may be the only choice to demonstrate BE.

Clinical Endpoints

Clinically meaningful endpoints should directly measure how a patient feels, functions, or survives, and represent or characterize the clinical outcome of interest. It is critical to ensure that the proposed clinical endpoint(s) are valid for evaluating treatment of the disease of interest; for a drug with multiple indications, the indication can be accurately diagnosed, and the treatment effect or clinical improvement with regard to this indication is well defined.^[2] In ANDA submissions, there are usually two types of clinical endpoints: continuous endpoints (e.g., number of lesions) and dichotomous endpoints (e.g., clinical success/failure). In this article, we will give a general introduction to the statistical approaches used in assessing BE with regard to these two types of clinical endpoints. See the work of Grosser et al.^[3] for a more comprehensive discussion on BE for generic locally acting drug products.

Statistical Approaches

Let us consider a parallel designed clinical endpoint BE study with three treatments: the test product (T), the reference product (R), and the placebo (P). To demonstrate

BE between T and R , one needs to show that T and R are equivalent, and that both T and R are superior to P .

Equivalence Analysis

The analysis of continuous clinical endpoints is similar to the analysis of PK endpoints, but under parallel design. The compound hypotheses to be tested are as follows:

$$H_0 : \frac{\mu_T}{\mu_R} \leq \theta_1 \text{ or } \frac{\mu_T}{\mu_R} \geq \theta_2 \quad \text{vs.} \quad H_A : \theta_1 < \frac{\mu_T}{\mu_R} < \theta_2,$$

where μ_T is the overall mean of T , μ_R is the overall mean of R , and θ_1 and θ_2 are the BE margins. Note that in generic drug development, θ_1 and θ_2 are recommended by the FDA in product-specified guidance (PSG) for every specific reference product. Generally, $\theta_1 = 0.80$ and $\theta_2 = 1.25$ are used. The null hypothesis H_0 is rejected if the 90% CI for the estimated mean ratio is contained within the interval $[\theta_1, \theta_2]$. Rejection of the null hypothesis H_0 supports the conclusion of equivalence of T and R . Note that for multicenter studies, it is important to investigate the site effect and the site-by-treatment interaction.

It is also worth mentioning that for nasal spray products, we usually adjust the analysis for the baseline value.^[26] Fieller's method^[27] is one of the commonly used methods to calculate the 90% CI for the estimated mean ratio in clinical endpoint BE studies. Exact methods of calculating the 90% CI have also been studied by Locke^[28] and Chow and Shao.^[29] Note that the parametric models generally assume that the data fit the normal distribution. If the assumption is violated, one alternative is to perform a nonparametric test such as rank test. However, it may not be appropriate if the quantity of clinical interest is the mean value instead of the median. Also, nonparametric methods are usually less powerful compared to parametric methods.

For dichotomous endpoints, we consider the compound hypotheses:

$$H_0 : p_T - p_R < -\theta \text{ or } p_T - p_R > \theta \quad \text{vs.} \\ \in H_A : -\theta \leq p_T - p_R \leq \theta,$$

where p_T is the success rate of T , and p_R is the success rate of R . The null hypothesis H_0 is rejected if the 90% CI for the difference in success rates between T and R is contained within the interval $[-\theta, \theta]$. Rejection of the null hypothesis H_0 supports the conclusion that T and R are equivalent. Wald test with Yates' correction^[30] is commonly used for calculating the 90% CI. Other methods such as Z-test have also been used in the literature, which produce similar results as Wald test.

Study Sensitivity

The superiority tests of each active treatment (T or R) over placebo should be conducted at a significance level of 0.05.

For continuous endpoint, we can use an analysis variance model to calculate the p -values for the superiority tests and compare them to 0.05. For dichotomous endpoints, Fisher's exact test or Chi-square test can be used to calculate the p -values for the superiority tests and compare them with 0.05. Failure of superiority tests suggests that the clinical endpoint BE study may not be sensitive enough to detect the difference between T and R .

DISCUSSION

This article introduced the definition of BA/BE, the development of BA/BE, and the methods and types of studies for determining BA/BE. Furthermore, we extensively discussed the study designs and statistical approaches to demonstrating BE in comparative PK studies and comparative clinical endpoint studies. We introduced the ABE, PBE, and IBE approaches in PK BE studies and their properties. Reference-scaled ABE approaches used for HV drugs and NTI drugs were also elaborated upon, referring to the FDA's product specific guidances. Typically used approaches for continuous endpoints and dichotomous endpoints in the clinical endpoint BE studies were presented for both equivalence analysis and superiority analysis. In vitro comparison was not discussed in this article. But it is worth pointing out that physicochemical characteristics can be identified and qualitatively (Q1) and quantitatively (Q2) compared for formulations that are chemically equivalent using in vitro studies. However, this method is only sensitive and reproducible when there is a reasonably well-characterized mechanism of action, and the specific contributions of the various physicochemical characteristics to the therapeutic effect of the active pharmaceutical ingredient at the site of action are well characterized. The interested reader can refer to the FDA's documents,^[31,32] Chow et al.,^[33] and Yu and Li.^[2]

Furthermore, certain products have other additional types of studies recommended to show equivalence between brand and generic. For example, in addition to a PK BE study, the development of transdermal delivery systems (TDSs) also requires two additional studies for efficacy and safety concerns: adhesion study, and skin irritation and sensitization (I/S) study. Adhesion study and skin I/S study are used not only in generic drug development but also in new drug development such as patch size modification. Instead of demonstrating T and R to be equivalent, these types of studies require demonstration that T is not inferior to R , which means T can be statistically better than R . In the adhesion study for generic TDS products, a new approach based on the mean difference has been proposed to replace the previous recommendation of using the mean ratio,^[34] and significantly refined the comparison criterion for well-adhering products. As we can see, the regulatory approaches have been well established for BE assessment. However, with more and more

generic products being developed, the traditional BE methods, e.g., "one-size-fits-all" rule, have been challenged and changed to move toward a more mature direction. The development of statistical approaches for BE assessment of HV and NTI drugs has amply borne this out. Innovative approaches and techniques are also emerging to deal with the new scientific and technical developments in generic products. For example, a new in vitro release test has been studied and recommended for BE assessment of acyclovir in FDA's recent guidance, providing a feasible in vitro comparison for products that are Q1 and Q2 same.^[34] Moreover, BE assessment has also been investigated for other types of drugs such as liposomal drug products, drug products acting locally within gastrointestinal tract, and long-acting injectable products. The interchangeability between a brand-name drug and its generic drugs, and the interchangeability among generic drugs have also been discussed.^[35–37] Many scientific and statistical issues in study design and BE assessment, such as missing data impact^[38] and choice of study population, need future work. For more information, the interested reader can refer to the works of Chow and Liu,^[39] Welage et al.,^[40] and Meredith,^[41] and references therein.

Abstract

This entry covers several important areas in bioinformatics including sequence analysis, genomics, proteomics, systems biology, genotype-to-phenotype mapping, and structural bioinformatics.

Keywords: Bioinformatics; Computational biology; Genomics; Microarray; Natural language processing; Proteomics; Protein structure; Sequence alignment; Sequence analysis; Systems biology.

INTRODUCTION

Broadly, bioinformatics as a field includes research in genomics, proteomics, computer science, pharmacology, drug discovery, and drug development. This review covers several important areas in bioinformatics including sequence analysis, genomics, proteomics, systems biology, genotype-to-phenotype mapping, and structural bioinformatics.

OVERVIEW

Bioinformatics is a broad field that covers many areas of computational research. There is not universal agreement on the definition of bioinformatics. Most narrowly, it refers strictly to the development of algorithms for sequence analysis. It can, however, encompass the development and application of computational tools across the scope of biology, covering molecular biology, cellular biology, and genetics. In this entry, we take the wider view and provide an overview of the major areas of biomedical computation.

Bioinformatics is a relatively new field whose development coincides with advances in personal computing and the development of the Internet. The Internet has given bioinformatics researchers the ability to provide on-line tools and data sets to the research community at large. The National Center for Biotechnology Information (NCBI) is the National Institute of Health's (NIH) public resource for organizing knowledge in biology. It provides access to scientific literature abstracts and citations, curated sequence data sets, and many public data analysis tools. Furthermore, the last few years has seen an incredible rise in genome annotation databases, such as the University of California Santa Cruz Genome Database and the Ensembl Genome Databases.

Research in bioinformatics is disseminated through journals and conferences. The most popular bioinformatics journals include *Bioinformatics*, *PLoS Computational Biology*, the *Journal of Computational Biology*, and *BMC Bioinformatics*, although bioinformatics papers are also published in *Genome Research*, *Genome Biology*, the *Journal of Molecular Biology*, and other common biological journals. In contrast to research publications in some other biology and medical fields, conferences and conference publications are important venues for the publication of bioinformatics. These conferences include the core annual conferences Intelligent Systems for Molecular Biology (ISMB), Research in Computational Molecular Biology (RECOMB), the Pacific Symposium on Biocomputing (PSB), the Computational Systems Biology conference (CSB), and the IEEE International Conference on Bioinformatics and Bioengineering (BIBE). RECOMB and ISMB move from year to year, while PSB is held in Hawaii annually, and CSB is held annually at Stanford University. The most prominent society for bioinformatics is the International Society of Computational Biology (ISCB), which currently has more than 2,500 members.

SEQUENCE ANALYSIS

The rapid development of technology for gene sequencing, motivated by the Human Genome Project, has caused the price for DNA sequencing to plummet, while the quantity of sequence data climbs. Although sequence data is abundant, functional information about genes, such as cellular localization, organ of expression, or time of regulation, is labor-intensive and expensive to acquire. Thus, the major bioinformatic challenge is to develop approaches to store, retrieve, and interpret genetic sequence data. To manage this

data, GenBank provides a repository of all publicly available DNA sequence. It currently contains over 38 billion bases of DNA sequences and is growing exponentially (<http://www.ncbi.nih.gov/Genbank/GenbankOverview.html>). With the recent development of high-throughput sequencing technologies and the production of full genome sequences, these challenges remain as relevant as ever. Previously perfected algorithms are now being adapted and scaled for new uses such as full genome alignment.

Another current bioinformatic challenge is the support of so-called next generation sequencing technologies that can identify millions of short sequences that need to be either mapped to a template genome or assembled into a *de novo* genome. These technologies generate sequence “reads” of 25 bases to more than 1,000 bases, depending on the platform. Each technology has its own data analysis needs, although the underlying principles are the same among them. A fundamental algorithm that underlies sequence analysis compares the similarity between pairs of sequences.

PAIRWISE SEQUENCE COMPARISON

As a result of evolution, many organisms share common ancestors. Homologous sequences, or sequences that share an evolutionary ancestor, between organisms often share function, even if the organisms diverged long ago. For example, nearly half of the genes known to be responsible for human diseases have a counterpart in yeast. Thus the function of an unknown sequence may often be inferred if a homolog has been characterized in another species. The problem then becomes one of finding homologs.

Although the sequences of homologs undergo mutations, enough similarities often remain so that they can still be recognized. Methods to recognize homologs must quantify the similarity between two sequences, while also being sensitive to changes. Particularly for proteins, some changes are more likely than others. For example, evolution is more likely to accept substitutions between similar amino acids, such as changing one hydrophobic amino acid to another. Such substitutions are less likely to have deleterious effects on the structure or function of the protein. Thus, sequence comparison methods should account for the severity of the change in the amino acid.

This problem has been addressed using dynamic programming, an algorithm developed in computer science.^[1] The biological adaptation of this algorithm, called Smith-Waterman after the inventors, finds and scores the optimal alignment between two sequences. A sequence alignment shows the association between each amino acid in one sequence with either an amino acid or a gap in the other. To find the optimal alignment, Smith-Waterman requires (i) a matrix of amino acid substitution scores and (ii) penalty scores for the opening of gaps in a sequence.

The score matrix contains the number of points to award when any two amino acids are aligned, that is, substituted for another. Substitutions between similar amino acids yield higher scores than those between amino acids that are different. One of the oldest matrices still in wide use is the percent accepted mutation (PAM) matrix.^[2] The PAM matrix was created by calculating, from hand-aligned sequences of protein families, the rate at which each amino acid is substituted for another. There are variations of PAM matrices that differ based roughly on evolutionary distance; empirically, the best performing version is PAM250. In this matrix, substituting a LEU for an ILE, two hydrophobic amino acids, is 2. However, changing the LEU to an ASP yields a lower score of −2.

In addition to a score matrix, Smith-Waterman requires a gap penalty. To handle insertion or deletion mutations (for DNA sequences), or inserted domains (for protein sequences), gaps may need to be opened in one sequence. A gap in one sequence can be interpreted either as an insertion in that sequence or a deletion in the other. Gap penalties are calculated with *open* and *extension* parameters. The *open* parameter is the cost of creating a new gap, and the *extension* penalty is the cost of lengthening the gap. Typically, these are found empirically.

In general, Smith-Waterman can comfortably detect homologous protein sequences if they share at least 30% sequence identity.^[3]

A powerful application of Smith-Waterman is to search a database (e.g., all known DNA sequences) for homologs to an unannotated query sequence. Unfortunately, with the size of current databases, such a search is too time-consuming for general use. Therefore, Basic Local Alignment Search Tool (BLAST) searches databases by using a heuristic that approximates Smith-Waterman.^[4] These approaches have also been extended to mapping sequences to the genome sequences, particularly the 10^6 – 10^8 reads with new high throughput sequencing technologies.

FINDING SEQUENCE MOTIFS

Although pairwise sequence alignment can detect homology, another type of sequence analysis is to search for specific subregions of sequences. Often, only a small portion of a protein confers its function. Instead of examining the whole sequence, another approach is to identify first the subsequence responsible for an interesting function, and then create a computational description of those residues, such that the description can be used to recognize other proteins with the same function.

Although there are many ways to represent functional subsequences, the two most popular ones are regular expressions and statistical profiles. PROSITE, a database of protein families and domains, uses manually created regular expressions.^[5] Regular expressions are well

understood, and there are existing algorithms to quickly find instances of these patterns in sequences.

However, regular expression patterns may not encode the subtleties required to recognize some functional sites. Therefore, statistical profiles are also used. Here, hidden Markov models have been found to perform well.^[6] A hidden Markov model encodes information about a protein family in *states* corresponding to residues or groups of residues that share a property. At specific states, certain amino acids may be more acceptable than others. For example, one state may prefer positively charged amino acids and will be more likely to *emit* one than one that is not charged. Thus, a hidden Markov model consists of hidden states that produce observed outputs, which are the sequences that belong to the protein family. Algorithms exist to train a hidden Markov model (calculate the probabilities that states emit amino acids) from a family of proteins, and to score a sequence against the model to determine whether or not it belongs to that family.

COMPARATIVE GENOMICS

Inexpensive gene sequencing technologies have led to the completion of thousands of genomes, including *Homo sapiens*, *Mus musculus*, *Drosophila melanogaster*, *Caenorhabditis elegans*, and *Saccharomyces cerevisiae*. The availability of genomes enables research in *comparative genomics*, which uses the genomes to discover biology, such as gene structure, gene regulation, and gene function. The main difficulty in comparing genomes is finding corresponding regions in the genomes of two organisms. Therefore algorithms have been developed to align genomes.^[7]

MICROARRAYS

Microarrays can quantitatively measure the relative abundance of short oligonucleotide sequences in a sample. There are two major technologies in use: one type, developed at Stanford, contains cDNA probes spotted on a glass chip, and the other type, developed at Affymetrix, contains oligonucleotide probes synthesized on a chip using a photolithography process. They were originally developed to measure simultaneously the expression levels of all genes in a sample of cells. With microarrays, scientists can assay for the genes that are expressed under experimental conditions, such as starvation, heat shock, or developmental stages. In each experiment, for each gene, microarrays produce a value whose magnitude is proportional to the amount of expressed mRNA present in the sample. However, microarray technology is not specific to gene expression and has also been applied to measure DNA in diverse genomic and epigenomic applications such as the presence of sequence polymorphisms, occupancy of transcription factors, or epigenetic methylation.

Although they have been in use for only decade, they represent an explosion in the amount of biological data available to the researcher.

One application of microarray data is to distinguish between subtypes of tumors.^[8] Identifying the correct tumor subtype can help doctors choose treatments that are more likely to be effective. Because the two main subtypes of diffuse large B-cell lymphoma have different genetic profiles, algorithms can differentiate a tumor based on its profile. Scientists characterized the expression profiles of tumors by using a method called *clustering*.^[9]

Clustering is often called an unsupervised method because it does not require prior knowledge about the data being examined. Given a list of genes, each with an associated expression profile, a clustering algorithm can group genes that exhibit similar profiles. An expression profile for a gene is a list of the expression values from microarrays collected across many different conditions, such as time points in a cell cycle or environmental conditions such as nutrient deficiency. Expression profiles for genes are often represented as a matrix, with genes on one axis and conditions on the other.

To find clusters of genes that exhibit similar patterns of expression, a clustering algorithm employs a *distance function* that quantifies the *distance* between the expression profiles of two genes. The more similar the profiles are, the smaller the distance. Conversely, very different profiles will receive higher scores. Although many distance functions have been applied, the Euclidean distance is used most often.

Applying the distance function to each pair of possible genes results in a matrix that contains the distances between genes. Finally, the clustering algorithm uses the distance matrix groups genes such that each group contains genes that are close to each other. There are two main approaches to this problem: K-means clustering and hierarchical agglomerative clustering. K-means clustering requires a parameter *K*, and produces exactly *K* groups of genes. *K* is often estimated based on prior biological knowledge. Hierarchical agglomerative clustering produces a hierarchical ordering of clusters, such that groups of very close genes are contained within larger clusters.

In addition to clustering, classification methods have been applied to microarray data. In contrast to the previous case, here, the goal is to distinguish between two known classes, such as patients with or without disease. Then, given a patient where it is not known whether they have the disease, the method can predict whether they also have the disease. Although many classification algorithms have been developed, such as Bayesian classifiers or Support Vector Machines, they all draw from the same principles. First is the requirement of a *training set* that contains examples of the two groups to be distinguished. Then, the algorithm is applied on a *test case* that is scored against the training set to identify the most closely related group.

Microarrays often need to be pre-processed before applying classification algorithms. Most importantly, they suffer from the *curse of dimensionality*, whereby the number of genes often exceeds the number of samples available. This causes theoretical problems. Because of the availability of many genes, it may be possible to find genes that can clearly distinguish the two groups based on noisy or arbitrary variations in the training data. Thus, microarrays undergo a pre-processing step that filters out the non-informative genes on the chip.

Because of the ability of microarrays to capture and quantitate the biology underlying disease, they are seen as a potential technology for delivering personalized therapeutics.^[10]

PROTEOMICS

Microarray experiments are exciting because they can simultaneously measure the activity of gene expression and regulation for an entire organism. Another important research area is understanding the activity of the *proteome*, the concentrations, structures, locations, and functions of the protein products of the genome. While experiments are not yet as technologically mature as genomewide microarrays, there are now powerful tools for measuring the diversity of the proteome at a point in time.

Two-dimensional SDS gel electrophoresis methods allow the researcher to separate the protein components of cytosolic extracts. The results of such separations gives a two-dimensional array of spots, each representing (if well separated) a single protein member of cell. Bioinformatics plays an important role in identifying and characterizing the specific spots in a gel. If a spot has not been previously identified or its identity is unclear, mass spectroscopy is a powerful technique for identifying the molecular components of a separated protein. Automated robots are becoming more common for coupling gel separation methods with mass spectroscopy for both separating and characterizing the protein components in a sample.

Proteomics methods can now identify peptides in a sample that is a complex mixture using mass spectrometry. Mass spectra are like “fingerprints” for the peptide that must be interpreted to identify the chemical structure of that peptide. Peptide spectra must be mapped to peptide sequencing with the use of a database driven search engine such as MASCOT, X-TANDEM, or SEQUEST. Search engines utilize large databases of known peptide spectra to make the identification.

The burden of bioinformatics methods is to automatically characterize previously known spots, to choose interesting spots, and to use the results of the mass spectrometry experiments based on genomic data, and to identify any covalent modifications (post-translational) that have occurred.

SYSTEMS BIOLOGY

An exciting goal of post-genomic science is to understand how genes and gene products interact on a cellular level, organ, and systems level. Systems biology is the emergent field aimed at modeling these processes. Cellular processes have been modeled as metabolic networks and gene regulatory (or genetic) networks. Biologically relevant networks are not limited to intracellular processes, but also include the immune system, embryogenesis, and development, as well as the interactions between cells. Bioinformatics' role in systems biology is to discover, characterize, store and simulate biological networks using experimental assay data. Networks quantifying the regulation and interactions of genes and gene products are generally divided into three areas: (i) metabolic networks; (ii) signal transduction networks; and (iii) genetic/transcriptional regulatory networks (GRNs). Because of the complex differences and cultural paths of research, prokaryotic networks are often considered separately than eukaryotic networks, although the underlying principles are generally similar.

The studies of metabolic networks have been undertaken for more than a hundred years. Traditionally, metabolic networks are elucidated by careful study of tissue and cellular extracts. Glycolysis was first investigated as early as 1860 by Louis Pasteur. Some of the early quantitative metabolic studies were undertaken by Hans Krebs, where critical components of the tricarboxylic acid cycle were deduced by determining the reactions that occurred in tissue. His account of this discovery can be read in *Perspectives in Biology and Medicine*.^[11] Today, metabolic networks are characterized through traditional biochemistry assays, and a combination of genomics and proteomics experiments.

To quantitatively analyze metabolic (or any kind of biological) networks, researchers must catalog network data in a manner that is conducive to quantitative studies. Such a resource is MetaCyc.^[12] MetaCyc is used for the study of metabolic network data and is annotated by hand using literature data, and contains nearly 450 pathways from over 150 organisms.

Signal transduction networks describe how molecular signals are received and propagated to the end result. While scientists have a broad understanding of the major backbone of signal transduction pathways, the challenge now is to characterize the interactions that are either transient or context dependent. Here, technological advances in the ability to measure simultaneously the phosphorylation of proteins or the expression levels of genes on a single cell level has provided deeper insight.^[13,14] Coupled with the development of experimental technologies, an active area is the investigation of computational approaches. A diverse array of tools have been proposed, including Bayesian networks, boolean algebra, and differential equations.

GRNs describe how gene transcription, translation, and modification are fundamentally controlled. Bolouri

and Davidson^[15] describe five methods in which genetic regulatory networks are characterized and reconstructed. Those are (i) gene discovery, (ii) regulatory linkage analysis, (iii) identification of transcription factor binding sites, (iv) kinetic data measurement, and (v) simulation of predicted networks.

Inference of phenotypic changes through biological networks is possible through direct simulation. Simulation of biological processes is possible with sufficiently quantitative and completed parameter sets. Several methods are characterized for the simulation and quantification of biological networks. Peleg et al.^[16] have described a method using Petri nets for quantifying biological networks. Random Boolean networks have also been extensively used to model cellular processes.

UNDERSTANDING THE RELATIONSHIPS BETWEEN GENOTYPE TO PHENOTYPE

With the development of powerful genomics assays and the sequencing of large genomic sequences, the study and annotation of genetic variation becomes a significant problem. This includes discovering alleles associated with a phenotype, understanding how these alleles mediate that phenotype, and how that genotype affects response to drug therapies. In humans, the most common form of variation is single nucleotide polymorphisms (SNPs), which occur approximately once every thousand bases in individuals. Other types of variation include small insertions and deletions (indels) and larger changes such as repeats, transposable elements, copy number variants (cnv), and longer insertions and deletions.

Several bioinformatics resources collect mutation data. dbSNP (<http://www.ncbi.nlm.nih.gov/SNP/>) is an interface to public SNP data, and currently contains over nine million submitted SNPs in humans. The HGMD (<http://www.hgmd.org/>) collects disease-associated mutations that are associated with specific loci. NCBI's dbGAP database manage genome wide genetic studies of complex diseases and phenotypes (<http://www.ncbi.nlm.nih.gov/sites/entrez?Db=gap>).

Understanding and predicting which variations are likely to participate in a phenotype is an important problem in bioinformatics. Initial research in this area has focused on SNPs and predicting which SNPs are likely to be deleterious.^[17–19] Several research studies have estimated the percentage of SNPs that are functionally important.^[20–22] These reports suggest that between 20% and 32% of amino acid altering (non-synonymous) mutations are likely to alter or damage the protein in which they occur. Many methods have been developed to predict disease causing mutations.^[23,24]

Pharmacogenomics is the study of genes, diseases, drugs, and the relationships between them. Primary to these efforts is understanding how different genotypes

lead to different patient responses to clinical treatment. To investigate this further, early research has focused on identifying how specific genotypes respond to different therapeutics. PharmGKB (<http://www.pharmgkb.org/>) is a public project that collects genotype and drug interaction data from several NIH-funded centers that are collecting this data.^[25] As soon as sufficient data are collected for different responses, genotypic assays can be developed as clinical diagnostic and treatment aids. Another aspect of this research is understanding the underlying molecular function of genome variation data. Two resources for annotating variation data with molecular function is MutDB (<http://www.mutdb.org/>), LS-SNP (<http://ls-snp.icm.jhu.edu/ls-snp-pdb/>), and PolyPhen (<http://tux.embl-heidelberg.de/ramensky/data/>).

STRUCTURAL BIOINFORMATICS

Proteins (and sometimes RNA) are large macromolecular machines that perform many of the basic functions of the cell. Understanding how the three-dimensional structure of a large macromolecule confers its function is an important problem in biology. Structural analysis bases many of its successes on the fact that the number of naturally evolved scaffolds, or structural folds, is finite. It is estimated that there are fewer than three thousand distinct folds found in nature.^[26] Currently, more than a thousand are known. This enables scientists to apply a guilt-by-association approach to predicting structure and function. An important area of bioinformatics research is collecting, storing, and retrieving structural data. The Protein Data Bank^[27] is a public resource for storing protein structure data, while the Nucleic Acid Database^[28] stores nucleic acid structures. ModBase^[29] is a resource that stores automatically predicted structures using the Modeller software package.^[30]

Several methods are available for annotating the function of a previously uncharacterized protein structure. Many of these methods rely on known functional annotations and detecting similarity in query proteins to those regions that have been previously annotated. A primary method for detecting similarity is through structural alignment—that is, aligning two regions of protein structures to identify similar regions. Structural alignment methods such as Dali^[31] and MinRMS^[32] characterize function based on structurally similar regions. MinRMS provides solutions to two problems. First, it determines which structural superpositions to evaluate, and then it determines which residues should be considered “aligned” or matched. To make the problem computationally tractable, superpositions are sampled by exhaustively evaluating all superpositions based on four atom clusters. All appropriate atoms are then sampled.

Other methods for functional annotation rely on matching similar structural properties. One such example is FEATURE.^[33,34] FEATURE encodes a local environment

of a protein structure as a vector of structural property values. Both supervised and unsupervised approaches can be used to assign function to previously uncharacterized protein structures.

Protein structure prediction methods are important for modeling structural effects in the protein products of genes of unknown structure. A primary consideration when building structural models is ensuring that the scientific question being asked can both be answered by a structural model and that the model you are building will be of high enough resolution to answer the question. There are two primary paths to building a model. First, comparative modeling methods are most often performed because they yield the best predictions. They require a target sequence that has a three-dimensional fold that is already known; in another, similar structure of detectably similar sequence.

Ab initio methods for protein structure prediction traditionally use biophysical first principles to attempt to “fold” a protein or RNA to its native three-dimensional structure. It is theorized that proteins adapt a state representing their minimum free energy. These methods are computationally challenging, because the force field used must be accurate enough to model the minimum free energy correctly, and the computational time required to model the folding is often impossible using even today’s fastest computers.^[35] Common force fields used for the simulation of macromolecules include AMBER,^[36] OPLS,^[37] and CHARMM.^[38] These force fields model the quantum effects of molecules as semi-empirical classical terms, parameterized from the theoretical and experimental properties of small molecules. The AMBER force field contains terms for bonds, angles, dihedrals, van der Waals, and coulombic interactions.

Simulation strategies implementing these force fields often involve focusing on parallelization to extend simulation time. With sufficiently parallel methods and hardware, simulations on the order of hundreds of microseconds are possible.^[39] This is nearing the time required to model adequately the folding of a quickly folding protein.

Homology modeling methods use the known structures of similar sequences to the target sequence to predict structure. These methods are usually performed in four or five steps: (i) fold identification; (ii) threading; (iii) modeling; (iv) model evaluation; and (v) refinement.^[30] Each of these five steps encompasses a large body of current research.

Commonly, choosing a fold or scaffold to use is relatively easy. Easier cases occur when a sequence being modeled has some recognizable degree of similarity with a sequence of known structure. When the sequence has diverged beyond the ability to identify the fold, more sophisticated methods must be employed.

Alignment of the sequence on the structure through the process of threading gives a prediction of how the backbone of the sequence relates to the backbone positions within the structure. Very generally, sequences of greater than 30% identity with a target are aligned by using sequence-based alignment methods, employing pairwise

residue matching scores, such as those outlined in “Overview.” When the difference is below 30% identity, more sophisticated methods may be required. These include statistical nonpairwise potentials,^[40] profile alignments (such as PSI-BLAST),^[41] or hidden Markov models such as those discussed previously.

Building a three-dimensional model based on a scaffold and a threaded alignment is a technically challenging task. The most commonly used package for modeling is Modeller,^[30] which employs a method based on satisfaction of spatial restraints. These spatial restraints are derived from the residue-residue distances in the known structures being modeled upon. After a sufficient number of restraints are determined, simulated annealing is performed to find satisfactory structures.

A notable method for building a model that does not require a similar template is the program Rosetta.^[42] Rosetta uses libraries of short peptide fragments of known structure. These fragment libraries are used to model the structural preferences of a local sequence. These predicted structural fragments are then used to predict the final structure. Modeled structures are often similar enough to deduce some of the topological components of the structure, but functional inference remains a difficult challenge with any modeling method not using a template scaffold as input.

Evaluation of modeled structures is performed by using both first principles, statistics of known structures, and experimental structural assays. Several stand-alone packages are available. The Biotech Validation Suite For Protein Structures (<http://biotech.ebi.ac.uk:8400/>), available at the European Bioinformatics Institute (EBI), provides three programs for structure analysis: Procheck,^[43] Prove, and WhatIf. Each of these applications provides a different aspect of structural analysis. Procheck checks a query structure for discrepancies with geometry, chirality, hydrogen bonds, disulfide bonds, dihedral angles, and so on. Prove performs an analysis of atomic volumes within a query structure. Finally, WhatIf analyzes rotamers, solvent atoms, proline ring puckers, bond angles and lengths, and atomic occupancy. Another package for structure analysis is Prosa II (<http://www.came.sbg.ac.at/Services/prosa.html>). Prosa II works by evaluating a model based on the knowledge of other known structures. Refinements of modeled structures is often performed by using molecular simulation methods or by re-performing one of the model building steps using different parameters.

ANALYZING BIOLOGICAL LITERATURE

Biological knowledge is still primarily disseminated as unstructured free text in textbooks, journal articles, and comments and description fields in databases. The amount of text available is increasing rapidly. MEDLINE currently contains over 12 million citations. Without specialized algorithms,

the knowledge encoded within the literature is inaccessible to computers. Therefore there is an increasing interest in developing bioinformatic algorithms to use the literature.

Having computational access to the knowledge within literature would benefit research and discovery in many ways. In the near term, it helps scientists to analyze their data more quickly by automatically identifying relevant keywords and articles. In addition, literature analysis has been used to improve homology search.^[44] Finally, there are efforts to develop algorithms that will help computers propose new hypotheses and guide experiments. Some have argued that automated analysis of all available literature, the *bibliome*, may uncover new associations that are currently unknown to scientists. This line of research stems from early work by Swanson, who discovered a new treatment for Raynaud's disease by matching its symptoms against drugs known to treat them.^[45]

LINKING BIOLOGICAL DATA TO TEXT

There has been much work in developing text mining algorithms to help make sense of biological data sets. Although there are many types of biological data available, such as structure, sequence, or expression, interpreting the data remains a primary challenge for biologists. Often, this requires literature searches to elucidate interesting features of the data. For aggregated data, such as protein families or genes sharing an expression profile, analyzing all their literature can be a daunting task. For these high-volume analyses, computational approaches can help collect literature relevant to data sets and then summarize interesting aspects of the literature.

Literature associated with protein sequences is often summarized by identifying the keywords that distinguish that set of sequences from a background set. Those keywords are the words occurring statistically more often with those sequences than with a background distribution of sequences. This technique is useful for annotating sequence families. Although there are many possible technical solutions for finding keywords, one of the earliest methods calculated the average frequency of words when they appeared with protein families and compared that against the number of families in which the word occurred.^[46] The interesting keywords were the ones that occurred very often, but with few families. Some of the protein families they annotated this way were *myoglobin*, *ras*, and *phosphoglycerate*.

A related task is to annotate sequences with structured descriptions of function, rather than just keywords. Rather than just identifying the discriminating words, this task aims to select, from a predefined list, the term that best describes the function of a sequence or sequences. One such list of functions is the Gene Ontology (<http://geneontology.org/>), which describes biological functions in three hierarchies, *Molecular Function*, *Biological Process*, and

Cellular Component. Here the task is to identify the *GO code* that best describes the literature associated with a sequence. This has been solved by using statistical *machine learning* algorithms that learn the characteristic features of each GO code, and can match the literature of a sequence based on which features they exhibit.^[47]

EXTRACTING RELATIONSHIPS

Finally, there is much work on identifying relationships present in text. There is much biological research concerned with discovering associations between entities, such as protein-protein binding or protein-drug metabolism. Because of the sheer number of relationships, manually creating lists of all known relationships is difficult. Thus there are bioinformatic algorithms to identify relationships from text and organize them into databases and networks.

The dominant approach for finding related entities is with co-occurrence. The theory behind this method is that related entities will appear in the same abstracts. Thus if two proteins bind to each other, they will occur in the same abstract. Although co-occurrence generates errors (e.g., not all proteins in the same abstract will be related), it works acceptably well for certain applications. One group has applied this method to create automatically regulatory networks.^[48]

TRANSLATIONAL BIOINFORMATICS

The National Institutes of Health (NIH) has recently started an initiative in translational medicine, the tight integration of clinical research and basic research. To enable this, they are funding Clinical and Translational Sciences awards to fund institutes and centers to enable translational research activities. Bioinformatics is a key area for developing translational research.

Important areas for development are in integrating large, de-identified clinical data sets with biochemical, genetic, proteomic, or other complementary data. This is an emergent field and is just being developed. A new conference, the Translational Bioinformatics Summit, is held annually in San Francisco to address research advances in this important area.

CONCLUSION

New topics in bioinformatics will likely continue to follow developments in experimental assays. The recent rise in new bioinformatics methods has not focused on advances in computational power, but on the development of complex assays for surveying the global activity of cells using proteomics and gene expression assays and the rise of the Internet.

Three areas that will continue to be of high importance to bioinformatics research are (i) simulation of biological networks to predict phenotypic changes, (ii) use of basic biology to influence clinical practice, and (iii) automation of complex bioinformatics methods. While these are certainly not the only growth areas, many problems remain unsolved within them.

In conclusion, bioinformatics is a broad and dynamic field that is constantly acquiring new challenges and insights from technology innovation throughout the biosciences.

Biologics

P. A. Lachenbruch, A. D. Horne, C. J. Lynch, J. Tiwari, and Susan S. Ellenberg

U.S. Food and Drug Administration, Rockville, Maryland, U.S.A.

Abstract

Biologics comprise products of wide-reaching public health impact, such as vaccines, as well as products, like gene therapies, that are on the cutting edge of science. This entry reviews the basic tenants of biologics and discusses some of the issues and regulatory processes in biologic products.

INTRODUCTION

The Food and Drug Administration (FDA) has six centers that review products for many uses. These centers are as follows:

- Center for Biologics Evaluation and Research (CBER)—regulates biologic products (e.g., blood products, vaccines, monoclonal antibodies, cytokines).
- Center for Devices and Radiological Health (CDRH)—regulates medical devices and radiation products (e.g., X-ray machines, cell separators, bandages).
- Center for Drug Evaluation and Research (CDER)—regulates drugs.
- Center for Food Safety and Applied Nutrition (CFSAN)—regulates foods and food supplements.
- Center for Veterinary Medicine (CVM)—regulates veterinary medical products.
- National Center for Toxicological Research (NCTR)—a research facility devoted to toxicology.

The origin of the regulation of biologics dates back to the Virus, Serum, and Toxin Act of 1902 that established the federal regulation of biologic products.^[1] Many provisions of that Act are still in force today: establishment licensing, product licensing, labeling requirements, facility inspection requirements, revocation or suspension of licenses, and penalties for violations. Initially, and until 1944, biologics were regulated by the Hygienic Laboratory of the Public Health Service. The laboratory promulgated regulations implementing the provisions of the Act. Inspections of manufacturing facilities were to be unannounced and conducted by commissioned medical officers. Samples of products were to be examined for purity and potency.

In 1944, there was a major revision of Federal public health laws. One change made was that “a biological license could [be] issue[d] only upon showing that the product and

establishment met standards to ensure the continued safety, purity, and potency of such products.”^[1] This act also provided for the transfer of biologics regulation to the National Microbiological Institute of the National Institutes of Health (NIH). In the 1950s, biologics regulation was transferred to the Division of Biologics Standards (DBS) of the NIH. In 1972, biologics regulation was transferred to the FDA, where it remains today. In addition to merging the DBS (renamed the Bureau of Biologics) into the FDA, the 1972 merger integrated the regulations of the Public Health Service Act and the Federal Food, Drug, and Cosmetic Act. In 1982, the FDA merged the Bureau of Drugs and the Bureau of Biologics into the Center for Drugs and Biologics; in the late 1980s, these were separated and became the CDER and the CBER.

OVERVIEW

The CBER’s responsibility includes blood and blood products such as immune globulins and clotting factors; therapeutic biologic products such as cytokines, monoclonal antibodies, and cellular and gene therapies; and vaccines and allergenic products. Formally, the Code of Federal Regulations (CFR) defines a biologic as “any virus, therapeutic serum, toxin, antitoxin or analogous product, applicable to the prevention, treatment, and cure of diseases or injuries of man.”^[2] Generally, biologics are products derived from biologic sources, tend to have a large molecular weight, are immunogenic, and exhibit pleiotropic effects (affect many different cell types). They have a prolonged duration of action and are more susceptible to microbial contamination than drug (CDER-regulated) products. Another important difference between biologic and drug products is that the organic materials used to make biologic products are more variable than the substances used in making drug products. The CBER considers the manufacturing process to be a fundamental aspect of the product and requires strict controls on this process. The manufacture of biologic products presents unique regulatory concerns in relation to quality control, consistency, stability, microbial contamination,

The views expressed in this document are those of the authors and do not necessarily represent those of the U.S. Food and Drug Administration.

product administration, and source of the material (serum, cell bank, and tissue). These products also present some special safety concerns related to the modulations of the immune system and the inflammatory response.

Blood and blood products include such items as immune globulin products, clotting factors for the treatment of hemophilia, products that test for human immunodeficiency virus (HIV) antigens, and products that promote cessation of bleeding, among others. The CBER is responsible for regulating the nation's blood banks to ensure a safe blood supply.

The spectrum of biologics for therapeutic applications includes monoclonal antibodies (derived from a single clone, used for diagnostic and therapeutic purposes), cytokines (proteins that mediate the effector phases of natural and specific immunity), hematopoietic growth factors (stimulate the growth and the differentiation of immature leukocytes in the bone marrow), cell and gene therapies, tumor vaccines, xenotherapies (products made from non-human sources), tissue-engineered products, and cell selection devices.

Vaccines are the most widely used class of biologic products that the CBER regulates. These products include polio, measles–mumps–rubella (MMR), diphtheria–tetanus–acellular pertussis (DTaP), *Haemophilus influenzae* type b (Hib), and hepatitis vaccines, as well as other vaccines that are less widely used, such as vaccines to prevent cholera and typhoid. The Office of Vaccines Research and Review within the CBER also regulates allergenic products to prevent or to reduce the effects of hay fever, allergies to grasses, and other allergic conditions.

A recurrent problem in evaluating some of the above types of products or procedures is that of competing risks. For example, in evaluating blood substitutes, a life-threatening safety event may cause the termination of therapy prior to a favorable outcome. When a favorable event (such as shortened hospitalization) and a competing event (such as death) have different implications for efficacy of the product, an assessment of product benefit may not be straightforward. Meinert^[3] noted that “a differential mortality by treatment group may influence the occurrence of nonfatal events. The treatment group with the highest mortality rate may have the lowest nonfatal event rate if death occurs before patients have a chance to develop the nonfatal event of interest.” The competing risk of mortality has little bearing on the evaluation of childhood vaccines, allergenics, and many other biologics.

REGULATORY PROCESS

Product Development and Licensure

The regulation of a biologic begins with the Investigational New Drug (IND) application, filed with CBER after preclinical testing suggests that a product may be safe and has

the desired biologic activity in animals. The clinical investigation of a new biologic, as well as a new drug, generally proceeds in three phases. Phase I studies are the first investigations in humans and focus on the safety, metabolism, and pharmacologic actions of the product, potential dose range, and sometimes preliminary evidence of effectiveness. Phase II studies are generally closely monitored controlled studies to obtain preliminary data on efficacy and side effects, and other risks, and to establish an optimum dose and schedule. Investigators often use data from phase II to determine appropriate endpoints for phase III studies. Phase III studies are larger studies of the efficacy and the safety of the product. They provide information to support risk/benefit considerations and form the basis for product labeling. After the completion of the investigational clinical trials in the IND phase, the sponsor submits a Biological License Application (BLA) to market the product. In order for a license to be issued, the application must show that the product meets standards of safety, purity, potency, and consistency of manufacturing, in addition to demonstrating efficacy. Following licensure, manufacturers are required to continue to monitor the safety of their products and to submit any reported adverse effects to the FDA.

Generic Products

The concept of a generic drug has not been applied to biologic products to date, as a result of the inherent variability in biologic products. Because the manufacturing process is a fundamental characteristic of the product, biologic products that are made differently are considered to be distinct. For example, although there are several DTaP vaccines, none is considered “generic”; they are all considered to be distinctly different products for the same disease indication.

International Harmonization

Since the early 1990s, a consortium of industry and regulatory scientists in the United States, Europe, and Japan has been working to harmonize the requirements for the licensure of drugs and biologics worldwide. This consortium, the International Conference on Harmonization (ICH), has developed a series of documents addressing wide-ranging issues in product development, including aspects of product manufacture, preclinical and clinical testing, postmarketing safety surveillance, and structure of reports to regulatory authorities. These documents have been adopted as regulatory guidances in the three participating regions.

ISSUES IN BLOOD AND BLOOD PRODUCTS

The CBER's Office of Blood Research and Review evaluates proposed studies of new products and the data that result, and conducts research related to the development,

manufacture, testing, and activities of blood products to ensure the safety of the blood supply (e.g., test kits for HIV, hepatitis B and C, syphilis), and those prepared by genetic engineering and synthetic procedures (plasma derivatives, oxygen therapeutics formulated by recombinant technology or purification), in order to establish standards to ensure the continued safety, purity, efficacy, and availability of blood products. The office evaluates study designs and licensing applications related to commercial blood-derived and analogous recombinant products distributed in the United States, such as medical devices used to collect, test, process, or store donated blood; retroviral diagnostic tests including HIV-related tests; and certain human cellular and tissue-derived products.

Many of the statistical approaches for addressing these activities are common to other biomedical evaluations and other centers at the FDA. In many conditions that blood products address, however, the target population is small, so sponsors must contend with limited numbers of patients available for conducting clinical trials. Evaluating the safety of blood and plasma products presents additional challenges. For many plasma products, many donations are pooled from a large number of donors. Thus a single donation of infectious but seronegative plasma or blood can affect many recipients. It is possible to reduce, but not entirely eliminate, the risk of transmitting infection via blood products. Donor questionnaires can identify some donors at elevated risk of having infectious blood; such donations are discarded. The application of nucleic acid testing (NAT) methods can document the presence of infectious agents before antibodies have been produced and therefore reduce the period during which an infectious individual will appear uninfected. The use of such methods permits a greater proportion of infectious donations to be discarded, further minimizing the risk of transmitting infection. Assessing new diagnostic test kits without the benefit of a “gold standard” is problematic, but sometimes unavoidable. In this case, the new test kit is compared with one in current use; but when the results are discordant, it is difficult to ascertain which test kit is superior. This situation leads to distinct statistical problems.^[4]

The primary endpoint or efficacy variable in any clinical trial should provide a convincing basis for comparing treatments. Biologic products sometimes address needs for which there are no currently existing products, so there may be no precedent for selecting an appropriate efficacy endpoint. The difficulty in defining an appropriate endpoint also arises in several types of blood product experiments. For example, fibrin sealants are products that are “painted” on a wound to halt bleeding. Should the endpoint be time-to-bleeding cessation, or the volume of blood loss? Should it be a dichotomous variable taking the value 1 if bleeding stops within some arbitrary time interval and 0 otherwise? What are appropriate comparator groups?

Hemophilia is the condition of a deficiency of clotting Factor VIII, and there are products designed to compensate

for this deficiency. Bleeding is often internal into a joint, however, and therefore not directly measurable. Because the bleeding causes the patient pain, bleeding cessation is measured by the patient’s subjective report that may be biased by the patient’s knowledge of the therapy. Also, it is common to assess multiple episodes of bleeding in such patients, leading to questions of how to account for the correlation among the responses.

In some cases, it has been difficult to conduct controlled trials when the investigational product was thought likely to be much better than existing therapy; thus some products have been assessed and approved on the basis of uncontrolled studies. In such cases, it has been necessary to determine a standard for comparison—either a historical control or an absolute standard.

Statistical Issues in Assessing Biologic Test Kits

The CBER regulates all products, including medical devices, related to assuring the safety of blood and blood products. These include various biologic test kits for detecting HIV, HCV, HAV, and HTLV. Within these larger groups, there are further categories such as HIV-1, HIV-2, and Type O kits. Kits are used for screening, diagnosis, and prognosis; some have been designed for home self-tests and also for quick responses in walk-in clinics. Kits may be designed to detect antigens or antibodies, using serum, plasma, sputum, or urine. The experimental studies for assessing test kits depend upon specific combinations of these reagents. The statistical design and analyses must be selected accordingly.

In evaluating a proposed test kit, the statistical approach consists of either comparing the proposed device to currently licensed devices, or requiring that the estimated sensitivity (the proportion of samples known to be positive that are correctly identified by the proposed kit as positive) and specificity (the proportion of samples known to be negative that are correctly identified by the proposed kit as negative) of the proposed device meet prespecified standards. In some cases, such as assessing a test kit proposed for a quick response, predicted value positive and predictive value negative may be the appropriate primary statistics of interest. Test samples that are indeterminate even after retesting are considered failures for evaluation purposes. Known positive and negative samples are those that had previously been so designated by some gold standard approved by the FDA. Because a kit proposed for screening purposes may be used subsequently to test hundreds of thousands or even millions of samples, it is necessary that the estimates of sensitivity and specificity be precise to as many as four decimal places. This level of precision requires 10,000 or more samples, considerably greater than those used for most other biologic assessments. Because of the required precision, it is preferable to use exact statistical computational methods in contrast to asymptotic approximations in computing estimates.

Predictive value positive (proportion of samples testing positive that are actually positive) and predictive value negative (proportion of samples testing negative that are actually negative) are occasionally the primary statistics of interest, in contrast to sensitivity and specificity. This might be the case, for example, when a result is of immediate importance and the patient may not return for confirmatory tests. A larger sample size is required for estimating predictive value positive and predictive value negative than is required when estimating sensitivity and specificity. Because predictive values are computed by a combination of the sensitivity, specificity, and prevalence, the variance depends on the variance of all three quantities.

Receiver Operating Characteristic (ROC) curves are occasionally proposed to the CBER for assessing biologic test kits. The CBER's practice with regard to ROC assessment has been to use criteria comparable to those provided in guidelines established by the National Committee for Clinical Laboratory Standards.^[5] These are especially useful when the diagnosis of disease depends on a continuous variable. For ROC curves, as with other statistical design issues, it is to the benefit of the study investigators to discuss potential issues, including sample size requirements, with representatives from the CBER before proceeding.

Low Prevalence Conditions

Some blood products are designed to treat rare diseases. Clotting factors for hemophilia, for example, are targeted at a total population of about 40,000 hemophiliacs in the United States. Some subgroups of this population have developed inhibitors to Factor VIII replacement products; treatments for such subgroups are aimed at much smaller target populations.

An even more extreme example is a product proposed for hemophiliacs who have developed inhibitors to the usual Factor VIII products. There are only about 400 patients in North America with this condition. For this product, it is feasible to recruit, at most, 20 patients for a clinical trial. These limited populations make it difficult to conduct clinical trials that can definitively establish efficacy or provide a substantial understanding of the safety profile of the product. Another rare condition is envenomation from snakebites. Only about 8000 people per year have sufficiently severe snakebites to be candidates for treatment. A new product under investigation was expected to provide the same therapeutic effect as the only currently available product, but with the hope that it would have a better adverse event profile. For this rare condition, an appropriate endpoint was needed; because mortality is uncommon, a score based on the severity of the snakebite was used. Because a great deal is known about the currently available product, both with regard to efficacy and safety, it was determined that the new study could be done using historical controls. The study showed that the

new product had a superior safety profile, and its efficacy appeared similar to that of the control, based on comparisons with historical data.

Conducting clinical trials involving few patients may require flexibility regarding some of the preferred characteristics of the ideal clinical trial. For example, it may be necessary to do single-arm studies and to compare results to historical controls. If a historical control group is used, it is important that control subjects meet the same entry criteria as the treated patients. The historical controls should be as contemporary as possible so that treatment characteristics other than the therapy in question are similar. Such rare diseases/problems are not unique to the CBER; indeed, the FDA has an orphan drugs office that helps to regulate therapies for these rare conditions.

Evaluating the Safety of Blood and Blood Products

Some blood and blood products are used to treat patients who donated the blood in the first place. These are called autologous products. Other blood and blood products are from donors other than the recipient (allogeneic products) and may contain viruses or other unwanted particles that could transmit disease to the recipient. Safety is a particular concern with allogeneic products because they are often administered directly into the recipient's bloodstream. Several procedures are used to reduce the risk of viral transmission from blood products:

- Blood collection centers screen donors for current and prior infectious diseases and high-risk lifestyle activities that could pose a risk of viral transmission from their blood or blood products.
- Blood collection establishments test all blood and plasma for HIV, HTLV, hepatitis B, hepatitis C, and other agents. Even with these procedures, occasionally (about one per 34,000 donations) a unit is virally contaminated, primarily because of the "window period" problem. The window period is the interval between the time an individual becomes infected and the time the virus (or antibodies to the virus) is at detectable levels in the blood. A blood or plasma donation made during the window period will not be identified as virally contaminated but may still transmit infection. The probability of a window period donation depends on the length of the window period and the effectiveness of predonation screening.^[6]
- Finally, plasma derivatives undergo viral inactivation treatment prior to distribution. This treatment reduces the risk of transmission of hepatitis B, hepatitis C, and other viruses to extremely low levels. Some nonenvelope viruses such as hepatitis A and parvovirus B19, however, are difficult to inactivate, so not all viral transmissions are affected by such procedures.

ISSUES IN BIOLOGIC THERAPEUTICS

The development of recombinant biologic products to treat human diseases has a relatively short history, although many “traditional” biologic products such as vaccines and blood products have a history of 100 years or more. During the last 10 years, scientific progress in recombinant DNA technology and molecular biology has resulted in new classes of products to treat diseases such as multiple sclerosis, hepatitis C, diabetic ulcers, and non-Hodgkin’s lymphoma and other cancers. The expanded development of therapeutic biologics is a result of new technology that permits molecular biologists to produce large quantities of previously scarce human proteins. Monoclonal antibody products have been developed for a variety of purposes, including the treatment of acute stroke, cancer, rheumatoid arthritis, and Crohn’s Disease; diagnostic imaging; and the prevention and the treatment of rejection of tissue grafts. Growth factor products are used for wound healing and for supporting the immune system in cancer patients receiving chemotherapy. Cytokine products such as the interferons and the interleukins are used to treat cancer, hepatitis C, and multiple sclerosis. Other biologic products have been developed for cystic fibrosis, anemia of chronic renal failure, stroke, myocardial infarction, and genetic disorders.

The fundamental principles of clinical trial and statistical methodologies applied in the area of biologic therapeutics are the same as in other areas of drug development. However, some statistical issues and design questions have been encountered in this area more frequently than others.

In the late 1980s to early 1990s, when alpha interferons, granulocyte colony-stimulating factors (G-CSF), erythropoietin, and other agents were entering Phase III trials, clinical studies were generally designed as superiority trials with concurrent placebo controls because they addressed clinical conditions for which there were no proven treatments. However, as these new agents came into clinical use, the trials of second-generation products were often designed with active control arms. These studies are usually designed now as noninferiority trials, with the objective being to rule out a specified (true) difference δ with specified power. In statistical terms, the null hypothesis is specified as $H_0: \mu_T < \mu_C - \delta$.^[7-9] The first generation of monoclonal antibodies for diagnostic applications as imaging agents has entered Phase III trials, and several have been approved. Clinical trials for diagnostic agents typically obtain images of patients using a conventional diagnostic method and images using the new method. Special problems with these trials include the fact that they are easily unblinded (images produced using radio-labeled monoclonal antibodies appear quite distinct from those produced by traditional imaging modes), and their overall performance is affected by the proportion of diseased patients in the study. Usually, the patient is imaged with both the standard method and the new method, and a comparison is made. These trials require methods that

account for the pairing of images. The traditional measures of efficacy of diagnostic products have been sensitivity and specificity—often considered as ROC curves. The gold standard is usually a histological measurement from a surgical procedure or a biopsy. Predictive values and accuracy are affected by the prevalence of the condition. Indeed, the measures themselves may be inappropriate in some instances. For example, if the objective is to detect the presence of disease in the patient (or an organ), sensitivity and specificity are appropriate. However, if the goal is the detection of lesions (affected areas), it is possible to ascertain the probability that an identified lesion is truly positive (positive predictive value). This may be of importance when the presence of a specific lesion (e.g., liver involvement) is directly related to treatment decisions. For example, in a colon cancer imaging product, the presence of four or more liver lesions is a contraindication to hepatic resection. A difficulty in assessing diagnostic success measures (sensitivity, specificity, negative and positive predictive values) is that areas that are not indicated as affected by the test product are not biopsied.

There is a need to have a carefully planned drug development strategy, and omitting intermediate phases is not generally advisable. The drug development plan may move gradually toward the more traditional paradigm of safety and efficacy evaluations as we identify more biologics that are safe and effective for the treatment of chronic diseases.

ISSUES IN VACCINES

Vaccines may be administered for either preventive or therapeutic indications. Preventive vaccines, which constitute the vast majority of vaccine products, typically are designed to elicit antibodies in healthy individuals to the causative agents for infectious diseases such as polio, diphtheria, tetanus, pertussis, measles, mumps, rubella, influenza, and others. Three major concerns addressed in preventive vaccine evaluation are the extent and the duration of protection from disease or infection, the characteristics of immune response, and the safety profile. Therapeutic vaccines are intended to treat an already existing disease, such as cancer or HIV, in the vaccine recipient. Because therapeutic vaccine trials are designed and statistically analyzed in the same manner as trials for other therapeutic products, they will not be considered further here.

An efficacy trial for a vaccine compares an investigational product to a control in an appropriate population. When the control is a placebo (or a vaccine that has no effect on the disease of interest), the trial can estimate absolute vaccine efficacy. When the control is an already licensed vaccine for the same disease indication, the trial can estimate relative vaccine efficacy.

For regulatory purposes, the main interest is in estimating the *direct* effect of the vaccine on disease incidence. Case definitions (criteria for the diagnosis of disease) must

be resolved in the planning stage. In general terms, vaccine efficacy is customarily estimated from a vaccine efficacy trial as:

$$VE = 1 - IR_v / IR_c$$

where IR_v is the disease risk, incidence rate, or hazard rate in the vaccinated group and IR_c is the corresponding estimate in the control group. VE might refer to absolute or relative efficacy, depending on the control group. There are a variety of methods for constructing confidence intervals around VE.^[10]

In addition to direct effects, vaccines often confer *indirect* effects as well, if the disease is spread by person-to-person contact in the population. In such cases, even persons who did not complete a vaccination series or are unvaccinated still may be protected from the disease because of a reduction in disease transmission. Thus undervaccinated or unvaccinated individuals may be protected from diseases through “herd immunity,” a phenomenon unique to vaccines. The direct estimates of VE obtained from clinical trials may underestimate the overall reduction in disease that might be expected in well-immunized populations postlicensure because such trials do not fully capture the likely indirect effects of vaccination. Much work on the estimation of indirect effects of vaccination has been done.^[11]

Often an investigational vaccine targets a disease for which an already licensed vaccine is available. In this case, the disease incidence may have already been reduced to such a low level that a clinical efficacy trial in that population is not feasible. For example, the recent trials for acellular pertussis vaccines could not be conducted in the United States because the long use of whole cell vaccines reduced the incidence of pertussis to extremely low levels. Thus trials of new acellular pertussis vaccines were conducted in Italy, Germany, and Sweden where vaccination with whole cell pertussis vaccines had been discontinued or was infrequent because of concerns about adverse reactions. Acellular pertussis vaccines were developed to reduce the adverse reaction rate.

Vaccine manufacturers attempt to combine several vaccines into a single product, when possible, to improve the efficiency of administration and to reduce the number of injections individuals must receive. Special issues arise in trials in which currently licensed individual vaccines are physically combined to be given as one injection and the resulting combination product is compared to the vaccines given separately. One concern is that mixing several antigens might result in reduced vaccine efficacy because some antigens may interfere with the immune response to other antigens. Another concern is that the evaluation of efficacy must be based on serological endpoints rather than cases of disease because of low disease incidence as a result of the wide use of the licensed component vaccines. Conducting and interpreting these trials are facilitated if there are prior data showing that certain serum antibody levels are correlated with protection from disease. In such cases,

the serum antibody levels can be compared to assess the noninferiority of the combination product. Unfortunately, such correlates are not known for all vaccines.

A third methodological concern in studies of combination vaccines is the assessment of local reactions. There is a single injection site for the combination product, while there are two (or more) injection sites for the separate products. Thus the separate injection treatment group has more opportunity to experience a local reaction (e.g., redness or swelling at the injection site) compared to the combination group.^[12]

When comparing a possibly improved vaccine (i.e., a vaccine with the same components as an available vaccine, but produced by a different sponsor or by a different manufacturing process and is intended to increase protection and/or to reduce side effects) or a combination vaccine to a standard licensed vaccine, the studies are usually designed as noninferiority trials, using immune responses (serological endpoints) as the primary outcome variable. In a noninferiority trial, in which proportions attaining some prespecified level of immune response are compared, the null hypothesis has the form $H_0: \pi_{v1} < \pi_{v2} - \delta$, where π is a proportion seroconverting or attaining a certain level of response, and δ is the decrease that can be tolerated.^[13] Unfortunately, the protective level of antibody (correlate of protection) is often unknown, thus complicating the establishment of an acceptable margin of equivalence (δ). The use of geometric mean tiers/geometric mean concentrations (GMTs/GMCs) to compare immunogenicity is often proposed because the titers or concentrations have been observed to have log-normal distributions. When GMTs/GMCs are compared, the hypothesis is expressed in terms of a ratio rather than a difference in proportions.^[14,15]

Studies to support consistency of manufacture are required for all products. Such studies are important because, as noted earlier, the manufacturing process is such an integral part of the product's license. These evaluations may be based on the physical characteristics of the vaccines, or may aim to show that successive lots of vaccine will evoke similar immune responses or bioassay results. The latter type, called clinical lot consistency studies, are usually designed and analyzed as equivalence studies (i.e., two-sided) because a difference in either direction is of interest.^[16] It is customary for at least three consecutively produced lots to be compared to establish the consistency of manufacture.

A change in a manufacturing process may occur after the completion of a successful efficacy trial. In this situation, there could be concern that the change may have resulted in a product that is no longer clinically equivalent to the one for which efficacy was demonstrated. This product change could occur if the manufacturing process affects the biologic variability of the product. To allay this concern, a “bridging study” may be conducted in which persons randomized to receive vaccine lots similar or identical to a lot used in the efficacy trial are compared to individuals randomized to receive the newly manufactured lots. Bridging

studies aim to demonstrate the clinical equivalence of the two sets of vaccine lots with respect to immune responses and various safety measures. If the lots are similar regarding these endpoints, then the efficacy and the safety that were observed for the lots used in the efficacy trial are inferred for the newly manufactured lots. A bridging study might also be conducted when there is a change in formulation or dosing schedule, as well as when the “change” is in a population for intended use that is different from the one in which the efficacy trial was conducted.

Bridging studies are usually much smaller than clinical efficacy studies because they rely on (continuous) immunogenicity measures rather than on detection of differences in small proportions acquiring the disease. Differences that may affect the vaccine’s immunogenicity include ethnicity, age, gender, and environmental factors. Generally, the goal of bridging studies is to show that the vaccines will provide similar levels of protection under the different conditions of use (i.e., lots, populations, combinations, etc.).

An evaluation of the safety profile of an investigation vaccine is extremely important. Because preventive vaccines are given to healthy populations, there must be assurance that serious adverse events associated with the vaccine do not occur at an unacceptably high rate. Large studies are usually required to allay this concern (e.g., if 3000 individuals were vaccinated with no serious adverse events being observed, the upper 95% confidence limit for the true rate of serious adverse events would be 0.001). One serious adverse event in a study of 4750 subjects would also yield an upper limit of 0.001. Less serious adverse events can have a somewhat higher bound of acceptability. A common local reaction (e.g., redness) at the vaccination site might be bounded at 0.05 or 0.10. Although local reactions can be attributed to the vaccine in nearly all cases, the causality of systemic events requires the comparison of rates in a controlled trial. The sample size requirement for assessing the common but less serious adverse events in controlled studies (e.g., a doubling of a 10% control event rate) is almost always met, as such differences can be reliably detected in studies of a few hundred people. Less common but more serious events, however, require much larger sample sizes than typically are needed to study efficacy. Ellenberg^[17] has argued that larger controlled trials would increase our knowledge about rare events prior to licensure and would assist in assessing spontaneous reports of events after licensure.

There are several open statistical issues in vaccine evaluation.

- *Evaluation of immune correlates of protection.* These immune response levels are surrogate outcomes for clinical vaccine efficacy that permit the evaluation of new vaccines more efficiently. The usual situation is to use the data from the clinical efficacy trials of the first generation of the vaccine and to attempt to correlate one or more measures of immune response, such as serum antibody levels, with vaccine efficacy. One

issue is determining the quantitative level of immune response that will afford protection from the disease, as well as the qualitative measure of immune response that is predictive of protection. A second issue regards how a surrogate relates to the causal pathway of the disease. Fleming and DeMets^[18] note that surrogates can be useful in phase II trials, but express concern over their use in phase III trials. They provide a number of examples in therapeutic trials in which information on surrogates has been misleading. A major concern is that a factor that affects the true clinical endpoint might not affect the surrogate. In vaccine trials, information on how the surrogate (qualitative measure and quantitative level of immune response) fits in the causal pathway of disease prevention is often quite good, but concerns arise in cases where no clear correlate of protection has been documented.

- *Selection of individuals and/or events to include in the primary efficacy analysis.* It has been a common practice to count cases only in subjects who received a full immunization series (usually with an additional time period to allow effective immune response to the full injection series). Cases occurring in subjects dropping out of the study, or cases of disease occurring before the full series are completed have often been ignored, or counted only in secondary evaluations. There are arguments against this type of analysis. Excluding dropouts affects the randomization and thus raises concerns about the validity of the statistical analysis. If subjects who become ill after the first dose do not complete the series and are then excluded from the efficacy assessment, the efficacy will be overestimated. Similarly, if subjects with adverse reactions fail to complete the series, both safety and efficacy will be overestimated. Thus many would argue for the study to be analyzed by counting all cases in all randomized individuals. This approach preserves the significance level if testing a null hypothesis that $VE \leq V_0$ (where V_0 is fairly large). In this case, the usual procedure is to compute sample sizes under the null hypothesis that $VE = V_0$. It can also be argued that the dropouts may be a nonrandom subset of the group that has been randomized with respect to the probability of disease, and that omitting them may lead to biased estimates of efficacy.

Practically speaking, in most vaccine efficacy trials, which enroll only healthy individuals, compliance with the full immunization series is quite high (often in the 90–95% range) and dropouts as a result of toxicity are not common, so that an intention-to-treat analysis and “full series” analysis often yield similar estimates of efficacy. Even when the two estimates diverge numerically, it has been observed that they tend to lead to similar conclusions about whether the vaccine works well enough (e.g., a VE of 0.85 or a VE of 0.65 indicates substantial efficacy). Thus unlike the situation in therapeutic trials in which the two

analyses may lead to conflicting conclusions about efficacy in part because effect sizes are frequently small and there is a much greater rationale for dropouts being a nonrandom subset of the study population with respect to the study outcome, the two types of analyses are likely to be concordant in vaccine trials. It is currently a common practice to perform both the full series analysis and the intent-to-treat analysis of preventive vaccine efficacy. A detailed discussion of this issue in relation to vaccine efficacy trials can be found elsewhere.^[19]

- *Evaluation of vaccines against a subset of pathogen strains.* In February 2000, the first vaccine against invasive pneumococcal disease for use in infants and children, Wyeth–Lederle’s PREVNAR®, was licensed. PREVNAR® is a seven-valent vaccine, containing polysaccharides from seven disease serotypes thought to be important causative agents, conjugated to a carrier protein. In a large efficacy trial, the vaccine was shown to be 100% effective in preventing disease caused by serotypes in the vaccine. That is, all protocol-defined cases of disease occurred in the placebo arm. No correlation between immune response and protection from disease could be determined.

The dilemma is how new pneumococcal vaccines will be evaluated. With an effective vaccine now available, it may not be possible to conduct a placebo-controlled trial of a new vaccine for the same disease indication. Clinical disease endpoint trials with PREVNAR® as the active control may not be possible, because disease incidence may be too low for required sample sizes to be feasible. It is possible that new pneumococcal vaccines will be evaluated using immune response endpoints, despite the fact that no correlate with protection from disease has been found.

Moreover, some of the new pneumococcal vaccines being developed will contain more than seven serotypes. In this case, the problem is how the new vaccines containing additional serotypes can be shown to be noninferior to PREVNAR®, which does not contain the additional serotypes. To what would the immune responses to the additional serotypes in the new vaccine be compared—a historical control or an external standard? How would the suitability of such comparators be determined? Another problem is that as the number of serotypes in the new vaccines increases (there are many serotypes that are causal agents), so does the statistical problem of multiple testing and its effect on error probabilities. This statistical multiplicity issue would have to be dealt with if the evaluation of a new vaccine were based on serotype-specific efficacy. Some suggestions have incorporated the basic idea of a composite index or score summarizing the overall response to all serotypes received. However, the validity of such measures would need to be assessed.

A related issue pertains to serotype replacement, for there are some pieces of evidence that vaccination against

certain disease serotypes may cause other serotypes to emerge dominant in a population. If a clinical disease endpoint trial were feasible, for example, in another country where disease incidence is still sufficiently high, could evaluation be based on protection from disease because of *any* serotype, as opposed to serotype-specific efficacy? The issue here is the determination of the appropriate outcome for establishing the efficacy of a vaccine. Which outcome has the greatest relevance to public health? Is public health benefit from vaccination best measured by serotype-specific efficacy, or by overall protection from the disease without regard to serotype etiology? A vaccine that is highly effective against diseases caused by serotypes in the vaccine—but does not reduce overall disease incidence in the population because of replacement serotypes—would not seem to be beneficial to public health. These issues are currently being considered.

- *Phase II studies of vaccines to prevent diseases with a behavioral component.* The transmission of some infectious diseases, such as HIV, is highly related to behavior. This leads to special problems when evaluating these vaccines in efficacy trials. For example, behavioral changes could impact the efficacy assessment of these vaccines; individuals who believe that they are protected by a vaccine may engage in more behaviors that expose them to infections. (This situation may be especially prevalent in individuals “self-unblind” by being tested for anti-HIV antibody.) Specifically, if more high-risk behaviors occur (because of a belief that the vaccine is fully protective), the incidence of new HIV infection may even increase, even if the vaccine has a modest protective effect. Similar concerns arise in trials of other diseases, such as genital herpes, which have a large behavioral component in their transmission.

On the other hand, intensive counseling aimed at limiting such behavior is usually considered as a mandatory part of the studies (either as a separate arm, or in both control and vaccinated groups). Such counseling may itself reduce the incidence of infection to an extremely low level, thus requiring much larger studies to demonstrate the efficacy of the vaccine candidate. If such counseling were not provided in clinical practice, the vaccine efficacy might be different (e.g., vaccinated individuals might engage in more high-risk behavior, leading to a lowered efficacy). In this case, a biologically effective vaccine might have a low “use effectiveness” in practice.

PHARMACOGENETICS AND DRUG DEVELOPMENT

Pharmacogenetics is the study of variability in drug response as a result of genetic factors. The field of pharmacogenetics is not new—experimental studies to examine

the genetic control of human drug response started in the early 1950s—but is rapidly expanding. The statistical and mathematical studies of genes in populations and families have a much longer history.^[20–22]

The spectacular advances in human genome sequencing and the development of microarray technology to measure gene expression patterns on a global scale have generated extraordinary levels of scientific excitement and research activity in pharmacogenetics.^[23–25] The major focus of the current research is on the identification of genes and gene products that are associated with various diseases and that may provide targets for new drugs and biologics. Investigators are also searching for genes and allelic variants of genes that affect patients' response to drugs. It may be possible to identify patients who respond to a particular drug (efficacy) without showing any adverse reactions (safety).^[26–29] Methodologies from statistics and bioinformatics are making significant contributions in this field.

Some progress has already been made. HERCEPTIN®, a genetically based monoclonal antibody, was licensed in 1998 for the treatment of patients with metastatic breast cancer whose tumor overexpresses the HER2 protein. This protein is encoded by the *HER2/neu* gene located on human chromosome 17q. The overexpression of HER2 protein is observed in only 15–30% of primary breast cancer patients, however.

Another interesting example is the effect of hepatitis C virus (HCV) genotypes on the efficacy of PEG–Intron/REBETOL in patients with chronic hepatitis C. The treatment response rate (loss of HCV–RNA) for patients with HCV genotype–1 (70–75% of all people with HCV infection) is approximately half of that observed in subjects without viral genotype–1 (41% vs. 75%). In hepatitis C, unlike metastatic breast cancer, all HCV genotypes do respond to PEG–Intron/REBETOL treatment, although some genotypes are more responsive than others. This PEG–Intron/REBETOL combination therapy was licensed for the treatment of hepatitis C by the CBER in 2001.

There are many design, analysis, and regulatory issues that are relevant to future trials incorporating pharmacogenetics. The regulatory approval of genetic tests (for patient screening, entry criteria, evaluation of endpoints, etc.) would involve the design and analyses of studies to estimate diagnostic success measures such as sensitivity, specificity, and predictive values. The number of patients with a specific genetic marker available for a clinical trial will depend on the frequency of that gene in the population; for rare genes, it may take many years to enroll sufficient patients in the trial. Study sample sizes will depend on observed associations between genetic markers and therapeutic response. If the patient population is heterogeneous, consisting of genotypes with different degrees of therapeutic response, the sample size and the trial duration would be increased compared to a study focused on a high-risk population. The differential effects of genotypes on the safety profile of the drug may affect the desirable size of

the safety database. Issues related to multiple comparisons, subgroup analyses, and alpha level may be important considerations in some trials. The examination of statistical issues in these areas is ongoing.^[30–32]

BIOTERRORISM PRODUCTS

In recent years, many countries have sought ways to combat biologic weapons that may be employed against them. Biologic weapons are based on bacteria, viruses, rickettsia, fungi, or toxins produced by these agents and could cause mass morbidity and mortality. The agents thought to be most likely used in this regard are anthrax, smallpox, and plague. Ways of protecting against the impact of bioterrorist attacks include vaccines, antibiotics, and antiviral products. A special challenge arises in the evaluation of these products because the types of exposures that a population might face as a result of a bioterrorist attack generally do not occur in nature. Thus it is not possible to evaluate a vaccine against bioterrorism in a clinical study. Challenge studies, in which vaccinated subjects are deliberately exposed to the agent of concern, have been conducted for some vaccines (e.g., malaria and plague) but only in settings in which clinical disease is 100% curable with immediate treatment. That is not the case for the types of pathogens noted above, and hence challenge studies of vaccines to protect against these diseases would be unethical. For this reason, the development of reliable animal models is critical. For animal studies to be considered to provide adequate evidence of human protection, a sponsor must demonstrate that the selected animal species is a good model of the human response to the vaccine, and must show that a fully vaccinated animal is protected against the specified disease. A draft rule delineating the circumstances in which animal efficacy data will be accepted as a basis for the licensure of new vaccines and related products (e.g., immune globulins) has been proposed.^[33]

WEBSITES FOR FDA INFORMATION AND GUIDANCE DOCUMENTS

There are several guidance documents relating to biologics that are available on the FDA websites. The addresses for the FDA website and the ICH website are:

FDA website: <http://www.fda.gov/cber/guidelines.htm>

ICH website: <http://www.ifpma.org/ich5.html>

CONCLUSION

Biologics comprise products of wide-reaching public health impact, such as vaccines, as well as products, like gene therapies, that are on the cutting edge of science.

Statistical issues can be complex and challenging. With the recent focus on vaccines and immunoglobulins against diseases of bioterrorism, as well as the new developments in pharmacogenetics, the field of biologics promises to be one of the most exciting and fertile areas on the frontiers of scientific investigation.

ACKNOWLEDGMENTS

We thank Toby Silverman, Karen Goldenthal, and Douglas Pratt of CBER for incisive comments on this document. We also thank our other colleagues at CBER for providing us with many insights into the regulation of Biologics.

Biomarker Development with Applications to Genetics Data: Statistical Tests

Gang Zheng and Jungnam Joo

National Heart, Lung and Blood Institute, Bethesda, Maryland, U.S.A.

Abstract

This entry reviews some recent developments using receiver operating characteristic (ROC) analysis for gene expression microarray data. It also discusses several procedures for obtaining robust test statistics and provides an example of this type of testing.

INTRODUCTION

Biomarker development usually involves several phases. For example, Pepe et al.^[1] provided five phases of biomarker development in cancer research including preclinical exploratory studies, clinical assay development, retrospective repository studies, prospective screening studies, and cancer control studies. These phases can be used for a biomarker development of other diseases (such as cardiovascular disease and asthma) as well. Statistical methods are employed to pursue the specific aims for each of these phases. In early developmental phases of a biomarker, the ability of a biomarker to distinguish diseased from nondiseased subjects needs to be evaluated. Sensitivity and specificity are frequently used measures for a biomarker with binary outcomes in this context. If a biomarker has multiple or continuous outcomes, a receiver operating characteristic (ROC) curve is examined. Standard statistical testing methods are available for these analyses. In retrospective studies, on the other hand, the association between a biomarker and disease is usually tested. A number of statistical test procedures have been developed for testing the association in various situations.

Recent techniques such as gene expression microarrays and proteomics offer novel approaches in the identification of potential markers and promise an improvement in diagnostics and therapeutics development. However, due to the huge number of markers available for analysis, investigators are at great risk of false findings. Therefore, appropriate statistical methods and evaluations are essential. In the first part of this entry, we review some recent developments using ROC analysis for gene expression microarray data. Specifically, we review ROC analysis briefly and how it is applied to gene expression microarray data to evaluate the diagnostic accuracy of biomarkers selected from thousands of markers.

Testing association between a marker and a disease is an important component for detecting genetic markers.

In the second part of this entry, we review robust statistical tests for detecting genetic markers. One feature of the analysis for a genetic biomarker is that optimal statistical tests usually depend on the underlying genetic model, that is, the mode of inheritance corresponding to the recessive, additive, or dominant disease. For many complex diseases, however, the mode of inheritance is unknown. Mis-specification of a genetic model may have substantial impact on genetic marker development. Robust test statistics are useful in this situation. We discuss several robust procedures. To test genetic markers in association studies, several designs are available. We focus on two of them: case-control studies and the case-parents' trio design. The impact of diagnostic errors of cases and controls on an association test using the case-control design is discussed. An example of applying robust tests to linkage analysis using affected sib pairs is also presented. Conclusions are given at the end.

ROC ANALYSIS FOR GENE EXPRESSION DATA

ROC analysis is one of the most popular statistical methods that is used for evaluating the accuracy of diagnostic classification of a biomarker. For a biomarker with binary outcomes, a natural way of evaluating its performance is to examine its sensitivity (true-positive rate) and specificity (true-negative rate). The generalization of the concept of these statistics to continuous (or polytomous) outcomes yields the ROC curve. It is a plot of sensitivity (true-positive rate or TPR) vs. one minus specificity (false-positive rate or FPR), i.e., $\Pr(Y \geq c | D+)$ vs. $1 - \Pr(Y < c | D-) = \Pr(Y \geq c | D-)$ for a series of cut-off values c , where Y denotes the biomarker and $D+$ and $D-$ represent subjects with and without disease, respectively. Here, the assumption that higher values of Y are associated with disease is made. Fig. 1 shows an example of an ROC curve from a simulated continuous marker for 50 case and 50 control subjects.

Fig. 1 ROC curve

Mathematically, the ROC curve can be written as $ROC(t) = S_{D+}(S_{D-}^{-1}(t))$ for $t \in (0, 1)$, where S_{D+} and S_{D-} represent the survivor functions for Y in diseased and nondiseased populations, respectively. This curve displays the trade-off between sensitivity and specificity (increase in sensitivity comes with decrease in specificity by lowering cut-off value and vice versa). It is a monotonic increasing function from $[0, 1]$ to $[0, 1]$, and better tests have the ROC curve located closer to the top left corner. Various methods for estimating ROC curves in ordinal rating and continuous data are summarized in Pepe.^[2] Summary measures for evaluating diagnostic accuracy based on ROC curves include the true-positive rate corresponding to a given, acceptable false-positive rate, the area under ROC curve (AUC), and the area under ROC curve in a restricted range of false-positive rates (partial AUC). Evaluating the diagnostic accuracy of a biomarker using prespecified true- and false-positive rates is quite straightforward. For instance, if a biomarker has continuous outcome, one can test whether the true-positive rate is less than a prespecified threshold TPR_0 given an acceptable false-positive rate FPR_0 . From the definition and properties of the ROC curve, this null hypothesis can be written as $H_0 = ROC(FPR_0) = TPR_0$.^[1] If a biomarker is binary, the null hypothesis of $TPR \leq TPR_0$ or $FPR \geq FPR_0$ can be tested.

The AUC can be interpreted as the probability that the class prediction of a randomly chosen diseased subject is more indicative of disease than the class prediction of a randomly chosen nondiseased subject. From this concept, nonparametric estimations of AUC and its standard error are possible with the Mann–Whitney U -statistic.^[3] This index, however, has been criticized since a large part of the area comes from the rightmost part of the curve that includes false-positive rates of no clinical relevance.

This consideration leads to a partial AUC, the area under ROC curve over a range of relevant false-positive rates.^[4,5]

One example of the application of ROC analysis for biomarker development can be found in microarray studies. Gene expression microarray is a technology that monitors the expression levels of thousands of genes in different specimens. Among the wide range of objectives of this novel technology, one common objective is to predict the diagnostic class of a patient based on the gene expression profile of the disease tissue from that patient.^[6] By simultaneous screening of multitude of biomarkers, gene expression microarrays provide a great potential for improving diagnostic classification and therapeutics development. The accuracy of diagnostic classification, however, needs to be closely examined for its clinical applications. In this context, the application of ROC analysis is natural. Here, we review several steps in developing and evaluating diagnostic classification based on gene expression profiles.

The first step is called feature selection or gene selection, in which marker genes that are closely related to disease classes are selected. The number of genes studied in microarray analysis is usually more than several thousand, and a large portion of them is usually not informative. It is, therefore, not efficient to include all of them in a classification model. The most commonly used gene screening procedure is to rank genes based on the value of univariate test statistics. For example, one can consider t or Mann–Whitney statistics for binary classes and F -statistics for polytomous classes. A specified significance level will be used to select significant genes. Various methods for gene selection with consideration of multiple comparisons are proposed and summarized in Dudoit et al.^[7]

In the second step, classification models based on selected genes are determined. Dudoit, Fridlyand, and Speed^[8] provided a comparison of several methods. The methods they compared include nearest neighbors and several variants of linear discriminant analysis, as well as more complicated ones such as classification trees. One of their main conclusions is that the simple classifiers, such as diagonal linear discriminant analysis and nearest neighbor classification, perform well compared to more sophisticated methods.

Evaluating the performance of a classification model may be the most important step for its clinical application. Receiver operating characteristic analysis is most commonly used in this context. Previously mentioned measures (area under ROC curves and partial area under ROC curves) can be utilized to measure the ability of a predictor to distinguish between classes. However, the accuracy of classification cannot be properly evaluated when all samples are used to develop a classification model. If evaluation is performed on the samples that were used to develop a classification model, it is well known that the performance will be overestimated. When independent samples are not available, internal validation is necessary.

Steyerberg et al.^[9] evaluated the performance of several internal validation methods for classification models including split-sample, cross-validation, and bootstrapping approaches. In the split-sample method, data are split into two parts, one to develop the model and the other to evaluate its performance. Cross-validation is an extension of the split-sample method. In this method, the split-sample method is repeated so that all subjects have once served to test the model. The average is taken to evaluate the performance. The most efficient method they found for the logistic regression model is the bootstrapping approach in which bootstrap samples are drawn from the original dataset with replacement. Models are usually developed in bootstrap samples, and they are tested either in the original sample or in those subjects not included in the bootstrap sample. One can use incomplete validation in which the same genes are used throughout the process. However, it is always desirable to use complete validation that repeats the entire model development procedure including gene selection.

As we have reviewed, ROC analysis is useful for evaluating the diagnostic and prognostic classification based on gene expression. But its contribution to biomarker development using gene expression is more global. It has been used to evaluate reasonable statistics for gene selection,^[10] to define expression thresholds that yields reduced misclassification,^[11] and to compare various methods for preprocessing of microarray data.^[12]

ROBUST TESTS FOR BIOMARKER DEVELOPMENT

Two robust tests are useful in detecting genetic markers when the underlying model is unknown. Suppose we have a family of optimal test statistics $\{Z_i : i \in \Lambda\}$, where $\Lambda = \{1, 2, \dots, k\}$ is an index of k underlying models. For example, Z_1 , Z_2 , and Z_3 are optimal test statistics for the recessive, additive, and dominant models ($\Lambda = \{1, 2, 3\}$), respectively. Assume that, under the null hypothesis, each Z_i asymptotically follows a standard normal distribution and that their correlation matrix is given by $\rho_{ij} = \text{Corr}_{H_0}(Z_i, Z_j)$. If all Z_i are significant or none of them are significant at the usual $\alpha = 0.05$ level, we would reject or accept, respectively, the null hypothesis regardless of the underlying model.^[13] In general, however, when some Z_i are significant while others are not, using either Z_i would result in loss of efficiency when the model is mis-specified. Furthermore, the conclusion depends on the choice of test statistics. In practice, robust tests retaining high relative efficiency and being independent of model assumptions would be desirable.

Two robust tests, the maximin efficiency robust test (MERT) and the maximal test (MAX), have been studied in the literature.^[14–16] It has been shown that they are useful in biomarker development.^[17–19] Suppose that the true

model $s \in \Lambda$ with optimal test Z_s is unknown. Define the asymptotic relative efficiency (ARE) of a test statistic Z_i ($i \in \Lambda, i \neq s$) to Z_s as $\text{Eff}(Z_i : Z_s)$. Then, $\inf_{s \in \Lambda} \text{Eff}(Z_i : Z_s)$ is the worst ARE or the test Z_i over all possible true models in Λ . A good robust test should have the best ARE among all worst situations when the true model is unknown. The MERT, denoted by Z_{MERT} , is the test whose ARE reaches $\sup_{i \in \Lambda} \inf_{s \in \Lambda} \text{Eff}(Z_i : Z_s)$, i.e.,

$$\text{Eff}(Z_{\text{MERT}} : Z_s) = \sup_{i \in \Lambda} \inf_{s \in \Lambda} \text{Wff}(Z_i : Z_s)$$

From Gastwirth,^[14,15] when $\rho_0 = \min_{i,j \in \Lambda} \rho_{ij} > \delta > 0$ for some δ , MERT uniquely exists and is the convex combination of all Z_i . In general, obtaining MERT requires a numerical algorithm. In many applications, however, MERT can be written as a linear combination of the extreme pair, i.e., two tests with the minimum correlation. Suppose that the minimum correlation $\rho_0 = \rho_{i_1 i_2}$ is reached at two tests Z_{i_1} and Z_{i_2} , $i_1, i_2 \in \Lambda$. Then, a linear combination of the extreme pair given by

$$Z_{\text{COM}} = \frac{Z_{i_1} + Z_{i_2}}{\{2(1 + \rho_{i_1 i_2})\}^{1/2}} = \frac{Z_{i_1} + Z_{i_2}}{\{2(1 + \rho_0)\}^{1/2}}$$

asymptotically follows a standard normal distribution under the null hypothesis with ARE equal to $\text{Eff}(Z_{\text{COM}} : Z_s) = (1 + \rho_0)/2$. Thus, when $\rho_0 = 0.70$, its ARE is 85%. A large correlation between the extreme pair indicates that the family of models are “close” to each other while a small correlation represents a “wider” family of models. The necessary and sufficient condition for Z_{COM} to be the MERT for the family of statistics $\{Z_i : i \in \Lambda\}$ is that

$$\rho_{i_1 j} + \rho_{j i_2} \geq 1 + \rho_{i_1 i_2} \quad (1)$$

for each $j \in \Lambda$. Condition (1) may not be easy to verify analytically. When the minimum correlation ρ_0 is small, MERT and Z_{COM} may not be sufficient. From Freidlin et al.,^[16] a maximal statistic (MAX) should be used when $\rho_0 < 0.50$ and the MAX and MERT (and Z_{COM}) have similar power robustness when $\rho_0 \geq 0.75$. The MAX defined in Freidlin, Podgor, and Gastwirth^[16] is $Z_{\text{MAX}} = \max_{i \in \Lambda} Z_i$. They also defined several simple versions of MAX such as $Z_{\text{MAX2}} = \max(Z_{i_1}, Z_{i_2})$, $Z_{\text{MAX3}} = \max(Z_{i_1}, Z_{\text{COM}}, Z_{i_2})$, where (Z_{i_1}, Z_{i_2}) is the extreme pair, or $Z_{\text{MAX3}} = \max(Z_{i_1}, Z_{i_2})$, where Z_j corresponds to some model between the extreme pair. For example, $Z_{\text{MAX3}} = \max(Z_{\text{REC}}, Z_{\text{ADD}}, Z_{\text{DOM}})$, where the recessive and dominant model is the extreme pair. The reason for considering MAX3 rather than MAX2 is that using only the extreme pair may not cover all underlying models in a family with a small minimum correlation. Thus, including the test corresponding to a model between the extreme pair would increase the power of the maximal test. In addition, the maximal test statistics over all models is hard to use in applications due to its unavailable asymptotic

distribution. Here, we focus on Z_{MERT} (or Z_{COM}) and Z_{MAX3} . For MAX3, we prefer $Z_{\text{MAX3}} = \max(Z_{i_1}, Z_{\text{COM}}, Z_{i_2})$ for two reasons. First, it takes the middle test that has equal correlation with each of the two extreme ones. Second, in simulation, it depends only on the minimum correlation.

The distribution and p -values of MAX3, $Z_{\text{MAX3}} = \max(Z_{i_1}, Z_{\text{COM}}, Z_{i_2})$, can be found empirically (similarly for MAX2 or other MAX3). Note that, under the null hypothesis, Z_{i_1}, Z_{i_2} asymptotically follow the bivariate normal distribution with zero means, unit variances, and the correlation matrix given by

$$\begin{pmatrix} 1 & \rho_0 \\ \rho_0 & 1 \end{pmatrix}$$

Hence, one generates a random sample of large size (n) from the bivariate normal distribution with the above correlation structure, where ρ_0 is evaluated using the observed data. For each replicate, Z_{COM} and Z_{MAX3} are calculated. So we obtain n Z_{MAX3} , which form an empirical distribution of Z_{MAX3} . The p -values can be obtained using tails of the empirical distribution.

EXAMPLES: APPLICATION OF ROBUST TESTS TO GENETIC ASSOCIATION AND LINKAGE

In genetics, a marker usually refers to a known physical location locus on a chromosome. It has at least two alleles that are different forms of the same gene. We consider a marker with only two alleles, denoted as M and N . This biallelic marker forms three possible genotypes: NN , NM , or MM . Each individual has only one of them at the marker locus. Define penetrances as the probabilities of disease given one of the three genotypes, that is, $f_0 = \Pr(\text{disease} | NN)$, $f_1 = \Pr(\text{disease} | NM)$, and $f_2 = \Pr(\text{disease} | MM)$. If there is no association between the marker and disease, the null hypothesis is $H_0 : f_0 = f_1 = f_2$. Otherwise, the marker is associated with the disease, in which case one of the alleles should have higher risk than the other, say, M is a high-risk allele and N is a normal one. So the alternative hypothesis is $H_a : f_0 \leq f_1 \leq f_2$ where at least one strict inequality holds. Using f_0 as a baseline penetrance, the null and alternative hypotheses can be equivalently stated using genotype relative risks, defined as $r_i = f_i / f_0$ for $i = 1, 2$. In genetics, a genetic model refers to a specific mode of inheritance corresponding to the recessive, additive, or dominant disease. In terms of penetrances, a genetic model is recessive, additive, or dominant when $f_0 = f_1$ (or $r_1 = 1$), $f_1 = (f_0 + f_2)/2$ [or $r_1 = (1 + r_2)/2$], or $f_1 = f_2$ (or $r_1 = r_2$), respectively.

Linkage studies are different from association studies. In linkage analysis, one tests if a marker and an unknown disease trait locus on the same chromosome are more likely to be transmitted together than expected to offspring. Linkage analysis usually requires genotype data

from several generations in order to determine the alleles shared identical by descent (IBD) by family members.

In association studies, many designs have been proposed to detect genetic markers. We review the use of robust statistics in two important designs. One is a family-based design using case–parents' trios^[20,21] and the other is population-based design using unmatched cases and controls.^[25] In linkage analysis, the design using affected sib pairs is illustrated.^[22,23]

Case-Parents' Trio Design

In this design, cases (diseased children) and their parents are ascertained from a population and their genotypes are obtained. For a marker with two alleles M and N , there are six possible parental mating types: (1) $MM \times MM$; (2) $MM \times NM$; (3) $MM \times NN$; (4) $NM \times NM$; (5) $NM \times NN$; and (6) $NN \times NN$, where “ $\times$ ” means mating, and parental genotypes are given on both sides of the mating “ $\times$ ”. The six mating types are given in the first column of Table 1. The second column gives case genotypes for each mating type and the third column is the count of sample size of trios (case and parents) under each mating type. The last three columns contain the probabilities of a case genotype given parental mating type and the disease status of offspring for the recessive (REC), additive (ADD), and dominant (DOM) models, respectively. The derivation of these probabilities can be found in Schaid and Sommer.^[21]

From Table 1, it is seen that mating types 1, 3, and 6 are not informative for the likelihood, as the corresponding conditional probabilities are constant. Thus, inference is based on mating types 2, 4, and 5. (Note that only two mating types are informative for the recessive or dominant model.) Conditional on parental mating and disease status, case genotypes of the six mating types are independent, although the noninformative mating types do not contribute to the likelihood function. Hence, for a given genetic model, the likelihood function is the product of the likelihood functions for the informative mating types with binomial distributions (mating types 2 and 5) and a multinomial distribution (mating type 4). Testing genetic association is equivalent to testing $H_0 : r = 1$. Denote the likelihood function for a given model as $L(r)$. The score test for $H_0 : r = 1$ can be obtained by

$$Z = \frac{\partial \log L(r) / \partial r}{\{-\partial^2 \log L(r) / \partial r^2\}^{1/2}} \Big|_{r=1} \quad (2)$$

For recessive, additive, and dominant models, respectively, (2) can be written as

$$Z_{\text{REC}} = (4n_{22} + 4n_{42} - 2n_2 - n_4) / (4n_2 + 3n_4)^{1/2} \quad (3)$$

$$Z_{\text{ADD}} = (n_{22} + 2n_{42} + n_{51} - n_{21} - 2n_{40} - n_{50}) / (n_2 + 2n_4 + n_5)^{1/2} \quad (4)$$

Table 1 Conditional Probabilities of Case Genotypes Given Parental Mating Types and Offspring Disease Status for Various Genetic Models

Parental mating type	Case genotype	Count	Conditional probability		
			REC ($r_1 = 1, r_2 = r$)	ADD ($r_1 = r, r_2 = 2r - 1$)	DOM ($r_1 = r, r_2 = r$)
1. $MM \times MM$	MM	n_{12}	1	1	1
2. $MM \times NM$	MM	n_{22}	$\frac{r}{r+1}$	$\frac{2r-1}{3r-1}$	$\frac{1}{2}$
	NM	n_{21}	$\frac{1}{r+1}$	$\frac{r}{3r-1}$	$\frac{1}{2}$
3. $MM \times NN$	NM	n_{31}	1	1	1
4. $NM \times NM$	MM	n_{42}	$\frac{r}{r+3}$	$\frac{2r-1}{4r}$	$\frac{r}{3r+1}$
	NM	n_{41}	$\frac{2}{r+3}$	$\frac{1}{2}$	$\frac{2r}{3r+1}$
	NN	n_{40}	$\frac{1}{r+3}$	$\frac{1}{4r}$	$\frac{1}{3r+1}$
5. $NM \times NN$	NM	n_{51}	$\frac{1}{2}$	$\frac{r}{r+1}$	$\frac{r}{r+1}$
	NN	n_{50}	$\frac{1}{2}$	$\frac{1}{r+1}$	$\frac{1}{r+1}$
6. $NN \times NN$	NN	n_{60}	1	1	1

$$Z_{\text{DOM}} = (n_4 + 2n_5 - 4n_{40} - 4n_{50}) / (3n_4 + 4n_5)^{1/2}$$

where $n_2 = n_{21} + n_{22}$, $n_4 = n_{40} + n_{41} + n_{42}$, and $n_5 = n_{50} + n_{51}$.

For recessive, additive, and dominant models, Z_{REC} , Z_{ADD} , and Z_{DOM} correspond to optimal test statistics, respectively. When the underlying genetic model is unknown, Zheng, Freidlin, Gastwirth^[24] showed that REC and DOM is the extreme pair with minimum correlation less than 1/3 and that condition (1) holds. Thus, Z_{COM} is the MERT. In Zheng, Freidlin, Gastwirth,^[24] $Z_{\text{MAX3}} = \max(Z_{\text{REC}}, Z_{\text{ADD}}, Z_{\text{DOM}})$ was studied. Here, we also consider $Z_{\text{MAX3}} = \max(Z_{\text{REC}}, Z_{\text{MERT}}, Z_{\text{DOM}})$. Table 2 presents an empirical power comparison of the three optimal test statistics as well as MERT and two MAX3. The simulation procedure was the same as described in Zheng, Freidlin, Gastwirth.^[24] Hardy–Weinberg equilibrium (HWE) is assumed with allele frequency $p = \Pr(M) = 0.2$, 100 case–parents’ trios and 10,000 replicates. The alternatives are chosen so that the optimal tests have approximately 80% of power. When the underlying model is unknown, the minimum power of each of the five test statistics across the three genetic models is highlighted. MAX3 and MERT have higher minimum powers across five models than optimal tests, which indicates the property of robustness compared to the three optimal statistics. Also, the two MAX3s perform similarly. Hence either one can be used.

Table 2 Empirical Power Estimates for the Optimal and Robust Tests for Trio Designs Under HWE and $p = 0.2$ with 100 Trios and 10,000 Replications

True model	Tests					
	Z_{DOM}	Z_{REC}	Z_{ADD}	Z_{MERT}	Z_{MAX3}^a	Z_{MAX3}^b
NULL	0.048	0.041	0.044	0.051	0.035	0.034
DOM	0.805	0.133	0.759	0.524	0.630	0.648
REC	0.121	0.796	0.459	0.656	0.702	0.698
ADD	0.783	0.297	0.801	0.704	0.671	0.677

DOM: $f_0 = 0.0200, f_1 = 0.0343, f_2 = 0.0343$.

REC: $f_0 = 0.0200, f_1 = 0.0200, f_2 = 0.0510$.

ADD: $f_0 = 0.0200, f_1 = 0.0325, f_2 = 0.0450$.

^a $Z_{\text{MAX3}} = \max(Z_{\text{REC}}, Z_{\text{MERT}}, Z_{\text{DOM}})$.

^b $Z_{\text{MAX3}} = \max(Z_{\text{REC}}, Z_{\text{MERT}}, Z_{\text{DOM}})$.

Unmatched Case–Control Design

The case–control design using population controls is an alternative approach. Data are displayed in Table 3 where cases and controls are sampled independently from their respective populations and their genotypes are obtained.

A linear trend test was proposed to analyze this dataset, which is obtained from a logistic regression model where genotypes are the only covariate.^[25] The genotype is coded using increasing scores as a covariate in the logistic regression model; that is, 0, x , and 1 for NN , NM and MM , respectively, where $0 \leq x \leq 1$. Optimal choices of scores

Table 3 Data of Case–Control Studies for Testing Association Between a Marker and a Disease

	Genotype			Total
	<i>NN</i>	<i>NM</i>	<i>MM</i>	
Cases	r_0	r_i	r_2	R
Controls	s_0	s_i	s_2	S
Total	n_0	n_i	n_2	n

are determined by the underlying genetic model.^[25,26] For recessive, additive, and dominant diseases, optimal scores are $x = 0$, $x = 1/2$, and $x = 1$, respectively. In general, the score x can be any value in the range $[0, 1]$. The trend test^[25] is a function of x given by

$$Z_x = \frac{\sum_{i=0}^2 x_i (Sr_i - Rs_i) / n}{\left\{ (RS/n^3) \left[n \sum_{i=0}^2 x_i^2 n_i - \left(\sum_{i=0}^2 x_i n_i \right)^2 \right] \right\}^{1/2}}$$

where $(x_0, x_1, x_2) = (0, x, 1)$. Under the null hypothesis, Z_x asymptotically follows the standard normal distribution. A procedure using isotonic regression and a pooled adjacent violator algorithm^[27] was used to determine whether or not Z_x is independent of the choice of x ,^[13] that is, whether or not $\min_{x \in [0,1]} Z_x$ is greater than or $\max_{x \in [0,1]} Z_x$ is less than the critical value (1.96 for a two-sided alternative with $\alpha = 0.05$). In either situation, we can reject or accept the null hypothesis regardless of the score x .

In general, when the underlying genetic model is unknown, Freidlin, Zheng, and Gastwirth^[19] studied two robust tests $Z_{\text{COM}} = (Z_0 + Z_1) / \{2(1 + \text{Corr}_{H_0}(Z_0, Z_1))\}^{1/2}$ and $Z_{\text{MAX3}} = \max(Z_0, Z_{1/2}, Z_1)$, and proved that $Z_{\text{COM}} = Z_{\text{MERT}}$. Simulation results in Freidlin, Zing, and Gastwirth^[19] showed similar patterns as in Table 2. To illustrate the use of robust test statistics, we apply them to a real dataset given in Shahbazi et al.^[28] to detect whether the epidermal growth factor gene is a biomarker for malignant melanoma. The data are summarized as $(r_0, r_1, r_2) = (6, 8, 10)$ and $(s_0, s_1, s_2) = (32, 47, 20)$. In Fig. 2, we draw the p -values for Z_x over all possible x . It shows that p -values depend on the choice of x . A conclusion cannot be drawn if there is no scientific knowledge about the underlying model for the choice of x . Hence, robust tests can be used as they are independent of x . From Freidlin, Zheng, and Gastwirth,^[19] p -values for Z_{MERT} and MAX3 were 0.041 and 0.031, respectively.

In case–control studies, the impact of diagnostic errors of cases and controls on trend tests has been recently examined by Zheng and Tian.^[29] Under the null hypothesis of no association between a marker and a disease, the diagnostic errors of cases and controls have no effect on Type I error. Under the alternative hypothesis, however, they have substantial effect on the power of case–control studies. To check this, we use an example given in Zheng and Tian.^[29]

**Fig. 2** p -Values of Z_x over all possible x

Taylor et al.^[30] examined a genetic marker for Alzheimer's disease (AD) in two different studies. The cases in the first study were autopsy-confirmed while in the second study they were clinically diagnosed. The observations for these two studies are given by $(r_0, r_1, r_2) = (67, 95, 45)$, $(s_0, s_1, s_2) = (95, 158, 37)$ and $(r_0, r_1, r_2) = (81, 116, 42)$, $(s_0, s_1, s_2) = (89, 111, 44)$, respectively. Comparing cases and controls with two copies of the risk allele, Taylor et al.^[30] found that the marker is associated with AD in the first study but not in the second. Using the score $x = 0$ in the trend test Z_x , Zheng and Tian^[29] obtained $|Z_0| = 2.659$ ($p = 0.008$) for the first study and $|Z_0| = 0.132$ ($p > 0.05$) for the second one. They further showed that, without diagnostic errors, the power for both studies would be about 95%. If one assumes that the cases in the second study were diagnosed clinically with 95% sensitivity and 95% specificity, then the power of the trend test reduces to 71%. This suggests that, when doing a confirmation study, the diagnosis criterion has to be the same as in the previous study.

Linkage Analysis Using Affected Sib Pairs

Any sib pair shares either 0, 1, or 2 alleles IBD at a marker locus. Denote the probabilities of sharing (0, 1, 2) alleles IBD as $p = (p_0, p_1, p_2)$ with $p_0 + p_1 + p_2 = 1$. For affected sib pairs, the null (no linkage) probabilities are $p_{H_0} = (1/4, 1/2, 1/4)$. Whittemore and Tu^[31] studied the following family of models for $p = (p_0, p_1, p_2)$:

$$\left\{ p : p = (p_0, p_1, p_2) = \lambda(0, x, 1-x) + (1-\lambda)p_{H_0} ; \right. \\ \left. \lambda \in [0,1], x \in [0,1/2] \right\}$$

The null hypothesis is $H_0 : \lambda = 0$ with a nuisance parameter x not defined under the null. Here x is related to the genetic model by $x = 0$ corresponding to rare recessive disease and $x = 1/2$ to additive disease. Among n affected

sib pairs, (n_0, n_1, n_2) are the observed counts for sib pairs sharing (0, 1, 2) alleles IBD. The score test for $H_0^{[31,17]}$ as a function of x can be written as

$$Z_x = \frac{n^{1/2} W_x (\hat{p} - p_{H_0})'}{\left\{ W_x \left(\text{diag}(p_{H_0}) - p_{H_0}' p_{H_0} \right) W_x' \right\}^{1/2}},$$

where $W_x = (0, x/(2(1-x)), 1)$, $p = (n_0/n, n_1/n, n_2/n)$, $i = 0, 1, 2$, and $\text{diag}(p_{H_0})$ is a diagonal matrix with the three elements equal to $1/4, 1/2, 1/4$, respectively. As the minimum correlation is 0.8165 between Z_0 and $Z_{1/2}$, MERT should be used where $Z_{\text{MERT}} = (Z_0 + Z_{1/2})/2(1.8165)^{1/2}$. Other optimal properties of this MERT in terms of power robustness and model selection were discussed by Whittemore and Tu.^[31] For another application in cancer area, see Cerami et al. (2014).^[32]

CONCLUSIONS

In this entry, we reviewed some recent developments for ROC analysis using microarray gene expression data and robust tests for identifying genetic markers. In the first part, several steps for developing and evaluating diagnostic classification based on the gene expression profiles were reviewed. In the second part, several robust tests were reviewed and illustrated, using three examples of detecting a genetic marker in association studies and linkage analysis.

ACKNOWLEDGMENT

Biomarker: Clinical Trials

Mark Chang

Veristat LLC, Southborough, Massachusetts, U.S.A.

Abstract

A biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacological responses to a therapeutic intervention. This entry discusses biomarker trial designs with classifier, prognostic, and predictive markers.

INTRODUCTION

What is a biomarker? The National Institutes of Health Workshop^[1] gave the following definitions. A *biomarker* is a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacological responses to a therapeutic intervention. A *clinical endpoint* (or outcome) is a characteristic or variable that reflects how a patient feels or functions, or how long a patient survives. A *surrogate endpoint* is a biomarker intended to substitute for a clinical endpoint. Biomarkers can also be classified as classifier, prognostic, and predictive biomarkers.

A **classifier biomarker** is a marker, e.g., a DNA marker, that usually does not change over the course of study. A classifier biomarker can be used to select the most appropriate target population or even for personalized treatment. For example, a study drug is expected to have effects on a population with a biomarker, which is only 20% of the overall patient population. Because the sponsor suspects that the drug may not work for the overall patient population, it may be efficient and ethical to run a trial only for the subpopulations with the biomarker rather than the general patient population. On the other hand, some biomarkers such as RNA markers are expected to change over the course of the study. This type of markers can be either a prognostic or predictive marker.

A **prognostic biomarker** informs the clinical outcomes, independent of treatment. It provides information about natural course of the disease in individual with or without treatment under study. A prognostic marker does not inform the effect of the treatment. For example, non-small cell lung carcinoma (NSCLC) patients receiving either epidermal growth factor receptor (EGFR) inhibitors or chemotherapy have better outcomes with a mutation than without a mutation. Prognostic markers can be used to separate good and poor prognosis patients at the time of diagnosis. If expression of the marker clearly separates patients with an excellent prognosis from those with a poor prognosis, then the marker can be used to aid the decision

about how aggressive the therapy needs to be. The poor prognosis patients might be considered for clinical trials of novel therapies that will, hopefully, be more effective.^[2] Prognostic markers may also inform the possible mechanisms responsible for the poor prognosis, thus leading to the identification of new targets for treatment and new effective therapeutics.

A **predictive biomarker** informs the treatment effect on the clinical endpoint. A predictive marker can be population-specific: a marker can be predictive for population A but not population B. A predictive biomarker, as compared to true endpoints like survival, can often be measured earlier, easier, and more frequently and is less subject to competing risks. For example, in a trial of a cholesterol-lowering drug, the ideal endpoint may be death or development of coronary artery disease (CAD). However, such a study usually requires thousands of patients and many years to conduct. Therefore, it is desirable to have a biomarker, such as a reduction in post-treatment cholesterol, if it predicts the reductions in the incidence of CAD. Another example would be an oncology study where the ultimate endpoint is death. However, when a patient has disease progression, the physician will switch the patient's initial treatment to an alternative treatment. Such treatment modalities will jeopardize the assessment of treatment effect on survival because the treatment switching is response-adaptive rather than random. If a marker, such as time-to-progression (TTP) or response rate (RR), is used as the primary endpoint, then we will have much cleaner efficacy assessments because the biomarker assessment is performed before the treatment switching occurs.

Biomarkers, as compared to a true endpoint such as survival, can often be measured earlier, easier, and more frequently; are less subject to competing risks; and are less confounded. The utilization of biomarker will lead to a better target population with a larger effect size, a smaller sample size required, and faster decision making. With the advancement of proteomic, genomic, and genetic technologies, personalized medicine with the right drug for the right patient becomes possible.

Conley and Taube^[2] describe the future of biomarker/genomic markers in cancer therapy: “The elucidation of the human genome and fifty years of biological studies have laid the groundwork for a more informed method for treating cancer with the prospect of realizing improved survival. Advanced in knowledge about the molecular abnormalities, signaling pathways, influence the local tissue milieu and the relevance of genetic polymorphism offer hope of designing effective therapies tailored for a given cancer in particular individual, as well as the possibility of avoiding unnecessary toxicity.”

CHALLENGES IN BIOMARKER VALIDATION

Relationships Among Biomarker, Treatment, and True-Endpoint

Validation of biomarker is not an easy task. Validation here refers to the proof of a biomarker to be a predictive marker, i.e., a marker can be used as a surrogate marker. Before we discuss biomarker validations, let's take a close look at the three-way relationships among treatment, biomarker, and the true endpoint. It is important to be aware that the correlations between them are not transitive. In the following example,^[3] we will show that could be is a correlation (R_{TB}) between treatment and the biomarker and a correlation (R_{BE}) between the biomarker and the true endpoint, but there is no correlation (R_{TE}) between treatment and the true endpoint (Fig. 1). Therefore, the proof of a relationship between the treatment and biomarker and a relationship between the biomarker and true endpoint does not lead to the proof of the relationship between the treatment and true endpoint.

Multiplicity and False Positive Rate

Let's further discuss the challenges from a multiplicity point of view. In earlier phases or the discovery phase, we often have a large number of biomarkers to test. Running hypothesis testing on many markers can be done either with a high false positive rate without multiplicity adjustment or a low power with multiplicity adjustment. Also, if model selection

procedures are used without multiplicity adjustment as we commonly see in current practice, the false positive rate could be inflated dramatically. Another source of false positive discovery rate is the so-called publication bias. The last, but not least, source of false positive finding is due to the multiple testing conducted by different companies or research units. Imagine that 200 companies study the same biomarker, even if family-wise type I error rate is strictly controlled at a 2.5% (one-sided) level within each company, there will still be, on average, 5 companies that have positive findings about the same biomarker just by chance.

Validation of Biomarkers

We now realize the importance of biomarker validation and would like to review some commonly used statistical methods for biomarker validation.

Prentice^[4] proposes four operational criteria: (i) treatment has a significant impact on the surrogate endpoint; (ii) treatment has a significant impact on the true endpoint; (iii) the surrogate has a significant impact on the true endpoint; and (iv) the full effect of treatment upon the true endpoint is captured by the surrogate endpoint. Note that this method is for a binary surrogate.^[5] Freedman et al.^[6] argues that the last Prentice criterion is difficult statistically because it requires that the treatment effect is not statistically significant after adjustment of the surrogate marker. They further articulate that the criterion might be useful to reject a poor surrogate marker, but that it is inadequate to validate a good surrogate marker. Therefore they propose a different approach based on the proportion of treatment effect on true endpoint explained by biomarkers and a large proportion required for a good marker. However, as noted by Freedman, this method is practically infeasible due to the low precision of the estimation of the proportion explained by the surrogate. Buyse and Molenberghs^[7] propose the internal validation matrices, which include relative effect (RE) and adjusted association (AA). The former is a measure of association between the surrogate and the true endpoint at an individual level, and the latter expresses the relationship between the treatment effects on the surrogate and the true endpoint at a trial level. The practical use of the Buyse-Molenberghs method raises two concerns: (i) a wide confidence interval of RE requires a large sample size and (ii) treatment effects on the surrogate and the true endpoint are multiplicative and cannot be checked using data from a single trial.

Other methods, such as external validation using meta-analysis and two-stage validation for fast-track programs, also face similar challenges in practice. For further readings on biomarker evaluations, consult Weir and Walley,^[8] who give an excellent review; Case and Qu,^[9] who propose a method for quantifying the indirect treatment effect via surrogate markers, and Alonso et al.,^[10] who propose a unifying approach for surrogate marker validation based on Prentice's criteria.

Fig. 1 Treatment-biomarker-endpoint three-way relationship

CLINICAL TRIAL WITH BIOMARKER

In reality, there are many possible scenarios: (i) same effective size for the biomarker and true endpoint, but the biomarker response can be measured earlier; (ii) bigger effective size for the biomarker and smaller for the true endpoint; (iii) no treatment effect on the true endpoint and limited treatment effect on the biomarker; and (iv) treatment effect on the true endpoint only occurs after the biomarker response reaches a threshold. Validation of biomarkers is challenging, and the sample size is often insufficient for the full validation. Given this reality, how we can use biomarker to help our clinical trial designs?

Adaptive Design with Classifier Biomarker

If evidence shows that the test drug might work better in some subpopulations with the biomarker than in those without the biomarker, we can design an adaptive trial in which the treatment effects will be evaluated for each of the subpopulations as well as in the overall population at the interim analysis. Based on the interim results, the second stage trial may be conducted on one of the subpopulations or on the overall populations. The adaptive design allows for combining the data from the first and second stages in the final analysis without undermining the validity and integrity of the trial. Statistically speaking, the family-wise false positive error rate is controlled.

Adaptive Design with Prognostic Biomarker

Insufficiently validated biomarker such as tumor response rate (RR) can be used in oncology trials for interim decision-making about whether to continue to enroll patients or not to reduce the cost. When the response rate in the test group is lower because of the correlation between RR and survival, it is reasonable to believe the test drug will be unlikely to have survival benefit. However, even when the trial stopped earlier due to unfavorable results in response rate, the survival benefit can still be tested. Chang^[3] discusses this for a Non-Hodgkin's Lymphoma (NHL) trial.

Adaptive Design with Predictive Marker

If a biomarker is proved to be predictive, then we can use it to replace the true endpoint from the hypothesis test point of view. In other words, a proof of treatment effect on predictive marker is proof of treatment effect on the true endpoint. However, the correlation between the effect sizes of treatment in the predictive (surrogate) marker and the true endpoints is desirable but unknown. This is one of the reasons that follow-up study on the true endpoint is highly desirable in the NDA accelerated approval program.

SUMMARY AND DISCUSSION

We have discussed the trial designs with classifier, prognostic, and predictive markers. These designs can be used to improve the efficiency by identifying the right population, making decisions earlier to reduce the impact of failure and delivering the efficacious and safer drugs to market earlier. Most recently, biomarker-driven adaptive design has become a very popular trial design for precision medicine.^[11] It, however, should be noted that, full validation of a biomarker is statistically challenging and sufficient validation tools are not available. Fortunately, adaptive designs with biomarkers can be beneficial even when the biomarkers are not fully validated. The technical aspects of adaptive design with biomarkers can be found in Chang's book.^[3]

Biopharmaceutics

Iain J. McGilveray

McGilveray Pharmacon, Inc., Nepean, Ontario, Canada

Abstract

This entry focuses on describing the essential features of biopharmaceutical characterization and testing of drug substances and products during their development.

INTRODUCTION

The biopharmaceutics and biopharmaceutical properties of a medicinal/drug product can be considered as the bridging information between physicochemical, pharmaceutical quality, and biological, pharmacological effects that result in therapeutic as well as toxic responses. The terms should not be confused with “biopharmaceuticals,” a term now being increasingly applied to active substances and products derived from biotechnology, such as the “recombinant” proteins.

Although regulatory documents, such as the Food and Drug Administration (FDA) guidelines for new drug applications,^[1] refer to biopharmaceutics and indeed the Code of Federal Regulations (CFR) require^[2] a separate biopharmaceutical review section in the new drug application (NDA), there does not appear to be an official definition of the term. The European regulations and the International Committee on Harmonization (ICH) guidelines have no direct reference to biopharmaceutics.

OVERVIEW

The term *biopharmaceutics* appears to have been first used in 1961 by Wagner^[3] to mean:

encompassing the relation between the nature and intensity of the biological effects observed in animals and man and, 1. the nature of the form of the drug (ester, salt, complex, etc.), 2. the physical state, particle size and surface area, 3. the presence or absence of adjuvants with the drug, 4. the type of dosage form in which the drug is administered, and 5. the pharmaceutical processes used to make the dosage form.

Gibaldi^[4] provided a brief definition of biopharmaceutics: “a major branch of the pharmaceutical sciences concerned with the relationship between the physicochemical properties of a drug in dosage form and the pharmacologic, toxicologic or clinical response after its administration.”

Biopharmaceutics is multidisciplinary, involving specialists in developing the chemistry and manufacturing control dossiers of applications and toxicologists and pharmacologists involved in documenting the pharmacokinetic and sometimes pharmacodynamic responses. Both groups apply appropriate statistical models with the advice of the statistical departments.

PROPERTIES

Biopharmaceutical properties are commonly divided into those intrinsic to the active substance and those of the finished pharmaceutical dosage form. The characteristics are defined during the development stages, which may be for the first entry of the substance or with a line extension using a different dosage form or even when generic products are being prepared. There are tests that are required only during development, and results of other tests that become the lot release specifications for each batch of substance and finished product prepared. In general, many of the physicochemical tests are used for quality control, whereas the pharmacological tests are rarely repeated postapproval.

Most of the literature on biopharmaceutics has been devoted to solid oral dosage forms of drugs that are absorbed from the gastrointestinal tract and are effective systemically. However, other routes, such as inhalation, dermal, and parenteral, also require biopharmaceutical evaluation.

Active (Drug) Substance: Physicochemical Characterization

Solubility

The aqueous solubility of the drug substance is established by obtaining saturated solutions at 37°C over 24 or 48 hr. In addition, pH/solubility profiles, at physiologically relevant values from 1 to 8, are measured. This information indicates if there might be a pH-dependent dissolution and

perhaps effects of food in delaying absorption. Substances with aqueous solubility higher than 1% are considered less likely to show solubility-limited absorption problems.^[5,6]

Intrinsic Dissolution Rate

Because this is surface area-dependent, it is defined as the amount of active substance per unit time that dissolves under standardized conditions of temperature, solvent composition, and liquid/solid interface. Commonly a nondisintegrating disk of drug substance provides the standardized surface area and liquid/solid interface.^[7] The United States Pharmacopeia (USP) has proposed an apparatus and a test to determine intrinsic dissolution.^[8] The cumulative amount dissolved over time per unit area is obtained, and data points were fitted with linear regression to obtain a slope, which is the intrinsic dissolution rate. There is a general agreement that the new drug candidates with intrinsic dissolution rates greater than 1 mg/min/cm² will have fewer absorption problems than those exhibiting rates below this level.^[5]

pK_a , Partition Coefficient, and Permeability

As well as bearing on solubility, the dissociation constant, pK_a , and partition coefficient between aqueous and organic solvents are important influences on the absorption of drugs.^[4] The lipid solubility of drugs is tested in partition experiments between buffer and such solvents as octanol, chloroform, and ethyl acetate. The majority of the organic small molecules are absorbed in the gastrointestinal tract by means of passive diffusion, with the transfer directly proportional to the magnitude of the concentration gradient across the membrane and the lipid/water partition coefficient of the drug. Because most drugs are weak acids or bases, present in the solution in both ionized and unionized forms, the unionized forms are usually lipid-soluble and can diffuse across the cell membrane. This was first proposed in the pH-partition hypothesis^[9] and, although it remains largely true that the pK_a determines the pH for the optimization of the unionized form, which will be more rapidly absorbed, the much larger surface area of the intestinal mucosa leads to a greater rate of absorption, even when the unionized form of the drug prevails at gastric pH.^[10] In addition to partition models, attempts to assess absorbability during development have involved in situ experiments with segments of animal intestine, such as the everted sac.^[11] However, more recently, the biopharmaceutics drug classification system has been promoted as being useful to predict absorbability properties.^[12] This system involves using measured human jejunal permeability^[13] and solubility properties to classify drugs into the following categories:

High solubility–high permeability
 Low solubility–high permeability
 High solubility–low permeability, and
 Low solubility–low permeability

It claims to provide a basis for estimating the absorption of drugs based on these properties of physiologic importance.^[12] This system is being used by the FDA to make decisions on postapproval changes^[14] and is also likely to be expected with the development information in NDAs.^[15] Currently, efforts are being made to search for other tests than human jejunal permeability to describe drug permeability. Such procedures as Caco-2 monolayer systems, rat intestinal models, and human mass balance are under consideration.^[15] Caco-2 increasingly is being used in fast throughput screening of drug candidates.

While many drugs are absorbed via passive diffusion, an increasing number are absorbed by special transporters.^[16] Examples are nutrient, vitamin, and ion transporters. Several cephalosporins and angiotensin-converting enzyme inhibitors are substrates for the intestinal dipeptide transporter. In addition, the role of *P*-glycoprotein countertransport processes in the intestinal mucosa is currently being elucidated and appears to be a significant influence on the bioavailability of some drugs, including verapamil and cyclosporin.^[17]

Particle Size, Surface Area, and Shape

Experiments in the development phase should determine if particle size will be a potential problem and if a batch specification is required. For sparingly soluble drugs, particle size is an important determinant of solubility. Enhancement of bioavailability by micronization to increase surface area was demonstrated for griseofulvin^[18] and spironolactone. However, for hydrophobic powders, micronization does not always lead to an increase in dissolution/absorption because aggregation may occur.^[19] For acid-labile drugs, an increase in particle size can lead to greater degradation in the gastric milieu.

The particle size of the inhalant dosage forms is an extremely important property for delivery to airways. Solution or suspension droplets from the delivery device aim to provide most of a dose with less than 5- μ m particles, sometimes termed as the *respirable volume*.^[20] For drug powder inhalers, powder rheology is complex.

Crystal Properties, Polymorphs, and Solvates

Polymorphism, the different arrangement of molecules in solid state, influencing physicochemical properties, needs to be investigated in development to decide if a batch specification is needed. Often, the less thermodynamically metastable form has more desirable solubility properties than the more stable polymorph. Depending on the rate of conversion of the metastable to stable form, it may be used in dosage forms. Examples include cimetidine^[21] and chlorpropamide.^[22]

Crystalline forms can also exist, with different external crystal shapes, or “habit.” Often, the solvent of crystallization will confer specific crystal properties that can

influence solubility. Although crystalline forms of erythromycin estolate had better dissolution properties than the anhydrous amorphous form, usually the amorphous powder of a drug substance is more soluble and bioavailable than the crystalline form. Examples of better properties with amorphous powders include chloramphenicol stearate, cortisone acetate, and novobiocin.^[23] Also, with ampicillin, the anhydrous form was found to be more soluble and gave greater bioavailability than the trihydrate.^[24] However, for carbamazepine, the dihydrate has better absorption properties than the anhydrous drug.^[25]

Stereochemical Characterization

Stereochemical molecules should be thoroughly investigated during drug development. In general, geometric isomers and diastereoisomers are considered separate chemical entities, unless there are interconversions among them or fixed ratios are important for clinical effect or stability. For enantiomers, the FDA has a 1992 Statement,^[26] and the draft ICH quality guideline 6A^[27] provides some advice. During the development, the chemical and biological stability of the enantiomers should be confirmed and the pharmacokinetic and other pharmacological properties of the individual compounds should be characterized. This will define the specifications required.

Stability

Stability, a key attribute that must be defined early in the development of a new drug candidate, includes degradative chemistry and physical form changes. These can be influenced by the route of synthesis and processing; but from the biopharmaceutical viewpoint, changes in the solubility and rate of dissolution among batches are signals of potential problems. Also, if a drug is unstable in the gastrointestinal milieu, such as degradation by hydrolysis, the alternatives include careful formulation (enteric coating) or a search for an ester resistant to hydrolysis. Although this attribute is defined in the Chemistry and Manufacturing submission file, such as advised in the ICH stability guidance,^[28] there are concerns about the potential effects on biopharmaceutics.

Salts and Prodrugs

While optimizing the stability and the biopharmaceutical properties of new drug candidates toward the formulation of consistent performance, the choice of free acid or base or salt form is important. Usually, the salt form of the weak base or acid drug made with the strong counterion, such as chloride or sodium, respectively, is more soluble and more rapidly dissolved than is the parent compound. Examples of basic drugs for which this prevails are the hydrochloride salts of epinephrine and quinidine; whereas for acids, such as barbitals, the sodium salt is

better dissolved. However, examples of free bases that are more soluble than the hydrochloride salt forms at gastric pH are chlortetracycline and methacycline,^[29] although the related tetracycline is marketed mainly as the hydrochloride salt. An interesting example is naproxen, which is formulated for chronic pain use as the acid, whereas the sodium salt (which is more rapidly dissolved) is prescribed for fast-acting analgesia.

In the preformulation assessment of inhalant dosage forms, the salt form is important.^[30] Many of the drugs formulated in these devices are weak bases prepared as salts, and the pH of solution with strong counterions such as chloride or sulfate could be problematic. Solutions with pH below 2 can cause bronchoconstriction, and thus weaker acid salts may have to be chosen.

Prodrugs are chemical modifications of drugs that are rapidly metabolized to active drug in the body, often at the intestinal villi. They are usually designed to be more lipid-soluble and thus provide better absorption. Ampicillin esters, bacampicillin^[31] and pivampicillin,^[32] were developed to improve the bioavailability of the active parent, ampicillin. Enalapril is the weakly active ethyl ester, converted to the diacid enalaprilat, which is a powerful angiotensin converting enzyme inhibitor.^[33] Valacyclovir is the L-valine ester of the active antiviral, acyclovir, which itself is poorly absorbed, and the de-esterification yields much higher serum concentrations of acyclovir by the oral route.^[34]

Excipients, Formulation Factors, and Manufacture

Overview

Drug product development has been described^[35] as a highly complex craft based on a substantial amount of empirical or semiempirical information in technical areas. The dosage form often assists or enhances bioavailability, with formulation components, but these may also hinder by accident or design (such as in prolonged-release/“sustained-action” products). Formulation development has been described as having three stages: formulation screening, formulation qualification, and production.^a For *screening*, small-scale studies examine the influence of excipients, together with the physicochemical properties of active substance, to target the critical qualitative components and their interactions. In the next stage, *qualification*, effects of quantitative composition, and potential critical variables of process are studied. Finally, in *production*, scale-up and batch-to-batch variables are examined, with validated in-process and final product quality tests, which apply specification standards developed from the knowledge obtained in the previous two stages.

^aDahl, E. Quoted in McGilveray, I.J. *Drug Inf* **1996**, 30, 1029–1037.

Formulation Components

In most cases, these are of pharmacopeial quality, although those not described in official compendia, which may derive from processed food components, should be approved by reference to lists such as the FDA “GRAS” list—generally recognized as safe. The European, Japanese, and U.S. pharmacopeias are working on a harmonization process in parallel with ICH (ICH Q4)^[36] to gain some form of mutual acceptance of excipients as well as for tests and standards (reviewed later). Major excipients are among the monographs being examined in this process. It should be noted that several formulating agents, such as starch, are multifunctional in solid oral dosage forms.

Excipients/Fillers. The amount of filler used relates to the potency of the drug. For low- and submilligram-unit-dose drugs, care is required to avoid adsorbent fillers because the small amount of drug may not be readily released after adsorption on the large filler substance. Lactose and starch are common agents, and variations in their physical properties can be problematic. For example, with salicylic acid, the type of starch used influences dissolution.^[37] Also, with sparingly soluble drugs, the solubility of the excipient influences the dissolution of the active substance. This was shown by the comparison of the dissolution rate of griseofulvin, which was much increased when a soluble carrier, rather than a hydrophobic carrier, was used.^[38]

Disintegrating agents. These substances are added to solid oral dosage forms to cause disintegration of the contents when ingested and exposed to aqueous gastrointestinal fluids. Common agents are processed carboxymethylcelluloses, starch (raw or processed, e.g., sodium glycolate), and Veegum.

Granulating agents and binders. These agents are added to a powdered drug to retain the integrity of the tablet or capsule contents and also to facilitate manufacturing. However, they can also affect dissolution and thereby absorption. Carboxymethylcellulose, gelatins, gums (such as acacia and tragacanth), polyethylene glycols, polyvinyl pyrrolidone (PVP), starch, and Veegum are commonly used agents. Banakar^[23] has reviewed the choice of such substances.

Lubricants. These are processing aids included to improve the flow of bulk granulations and to avoid their adhesion to tablet manufacturing parts. The amount and type of mixing can affect the dissolution properties and absorption of certain drugs because they are predominately hydrophobic compounds such as stearates and talc. Their presence, concentration, and blending with other components have been described^[39] as among the most important factors influencing dissolution/absorption because the substances can form a water-repellent coat

around each granule. More recent work^[40] has confirmed that the amount of magnesium stearate and the time and type of mixing (shear) can be important.

Surfactants (Wetting agents). Surface-active agents such as sodium lauryl (dodecyl) sulfate and polysorbate 80 and hydrophilic polymers such as PVP and Hydroxy Propyl Methyl Cellulose (HPMC) are used to improve the dissolution of sparingly soluble drugs in tablet or capsule formulations. Both their properties and manner of addition can influence the resulting dosage form. The effect on solubilization is concentration-dependent.^[41] Below the critical micelle concentration, drug absorption is enhanced; but above this concentration, a portion of the drug associated with the micelle is unavailable for absorption. These surfactants also influence membrane permeability, and higher concentrations should be used with caution because of potential toxic effects.^[29]

In ophthalmic dosage forms, water-soluble polymers, such as polyvinyl alcohol and hydroxypropylcellulose, have been used at low concentrations to prolong the residence times of the solutions on the eye surface and to provide low-viscosity products that do not interfere with vision.^[42]

Ointments and skin preparations. Preparation of topical skin preparation combines the art of formulation with physicochemical knowledge of the components. Barry^[43] provides an interesting protocol for optimizing a dermatologic formulation. The key question is whether or not percutaneous penetration is desired. The diffusant, vehicle, and state of skin treated and how these factors interact “influence” the penetration. In another monograph,^[44] the tremendous variety of formulation types is considered, including liquid soaks, liniments, lotions, gels, creams, and ointments. These are composed of several bases, including aqueous, powder, and oily components, with thickening agents, emulsifying agents, buffers, antioxidants, and preservatives. Among the ointment bases are hydrocarbon bases (petrolatum); soft and hard paraffins; fats and fixed oils, including mono-, di-, and triglycerides (such as from olive, sesame, and peanut oils); silicones; water-soluble carbonates, and absorption bases such as lanolin, cholesterol, sorbitum monostearate, and wool alcohols. These can be mixed to minimize or optimize skin penetration with particular drugs, and biopharmaceutical tests have been difficult to devise.

For transdermal penetration, both skin patches and ointments have been applied. With many drugs, the limiting absorption-through-the-skin barrier does not provide sufficient dosing, but it has been excellent when low, constant dosing has been required, e.g., estrogen, nicotine, and scopolamine.^[45] Some transdermal systems, as well as ointments, depend on the native rate-limiting skin permeability, and others include rate-limiting membranes. It is easier to devise biopharmaceutical tests for the transdermal systems than for the topical dermatologic agents because

with the transcutaneous absorption, the pharmacokinetics of the drug can be studied in the systemic circulation.

Formulation of inhalants. As with skin preparations, the formulation of inhalation delivery systems is complex.^[30] These include nebulizers, metered-dose, and drug powder inhalers, each providing their own challenge to the developers. The biopharmaceutical evaluation of metered-dose inhalers has been extensively researched in the last decade. Pharmacokinetic valuation is limited because less than 20% of the delivered dose enters through the airways, the residue being swallowed.

Atkins, Barker, and Mathisen^[30] examined the four separate components of metered-dose inhalers: (a) formulation (drug, excipients); (b) container; (c) metering device; and (d) actuator mouthpiece. There are two formulation types, solution and suspension, and both contain propellant. Solutions often contain cosolvents (usually ethanol).

Traditionally, chlorofluorocarbons were used as propellants. However, with the international banning of these ozone-destroying agents, there has to be a reformulation with more ozone-friendly hydroxy- and hydroxy-chlorofluoroalkanes. These have different compatibilities with the surfactant-dispersing agents, and their introduction to formulations has been a challenge after the toxicology screening was complete.

Manufacturing Process

The workshops on scale-up and postapproval changes (SUPAC)^[6,46] indicate that critical manufacturing variables should be researched during the formulation development. Also, the FDA project with the University of Maryland suggested a framework to map out such process variables; the approach is outlined by Shah.^[47] This explains that the critical manufacturing variables include manufacturing, formulation, processing, and equipment that can significantly affect drug release from the product. Examples of formulation variables were noted in “Formulation Components” and include particle size and ranges of magnesium stearate. Equipment differences, such as mixing shear, can be critical, and process variables include compression forces, impeller speed, lubricant blend time, and indeed, order and time of addition of ingredients in the “recipe.” In the complex system of the dosage-form manufacture, multifunctional influences affect dissolution and bioavailability, and knowledge of the key variables and validated tests and standards to control them is vital for consistent quality manufacture. Lukas^[48] has provided a useful review of examples of the manufacturing variables that have been shown to influence dissolution (and sometimes absorption).

Granulation. Granulation usually improves the dissolution performance of sparingly soluble drugs. Wet and dry granulation procedures are both applied. Although

wet granulation has disadvantages, particularly “clumping” for hydrolytically labile drugs, advances in equipment have helped to speed the process and minimize exposure times. Water content can be critical in this process, as an example with naproxen demonstrates.^[49] Less-granulating water exhibited faster dissolution, attributed to smaller granules and less residual moisture. The order of addition of microcrystalline cellulose for granulation was shown to influence disintegration and dissolution.^[40]

Compression. In general, it might be expected that harder tablets from stronger compression would tend to decrease dissolution rates. However, in fact, more complex relationships are described. In compression of powders with different particle sizes, there was an optimum size when bonding and separation of the particles were in equilibrium within a tablet.^[50] The manner of packing of contents also affects capsules, and the modern capsule machines also involve compression. An advice from Abdou^[29] is that a full dissolution/compression study for each granulated formulation is essential to determine the compression parameters that will ensure good dissolution characteristics and adequate bioavailability.

Mixing. Rekhi et al.^[40] and Bergman and Bandelin^[39] have indicated that the amount of lubricant, magnesium stearate, is a key variable in formulation. The type of mixing was shown^[51] to influence this variable in developing cefadroxil capsules. During scale-up, with a constant 1% magnesium stearate composition, a change of type of the capsule-filling machine resulted in a decrease of dissolution. This was found to occur, with the different machine, by a repeated shear in the powder tamping process, leading to the greater coating of the water-repellent lubricant on the drug particles.

Dosage Forms, Compendial Monograph Tests, and Standards

Because “Dosage Forms” is the topic of a separate entry, few details or definitions are provided here. They are defined (with some variations) in the pharmacopeias. Compendial monographs (European, Japanese, and U.S. pharmacopeias) are public standards using validated tests and standards. While applications for new drug products contain proprietary information, the ICH process encourages the use of tests and standards described in these pharmacopeias. This is particularly desired in specifications, as noted in the ICH quality guideline 6 (Q6A and B).^[27]

Dosage Forms

Solutions. These are used primarily in parenteral presentations. In general, the aqueous solutions are considered to have few biopharmaceutical risks. Stability is a key parameter. Unless they have different components, generic

parenteral solutions are waived from in vivo bioequivalence comparisons. Aqueous oral solutions are prescribed for children and the very old. Oily solutions are more subject to biopharmaceutical problems. Cyclosporin provides an example because its formulation in oily solution resulted in erratic absorption in patients.^[52]

Suspensions. Suspensions, which may be for oral or intramuscular administration, are less straightforward in absorption properties than are solutions. Oral suspensions are common as pediatric dosage forms, and these have demonstrated bioavailability problems, as found with phenytoin.^[53] Micronization of the drug resulted in a 50% increase in bioavailability. As well as particle size, viscosity and the use of suspending agents are important quality attributes of suspensions. Although dissolution tests for suspensions have been investigated, they are not yet official.

Capsules. Although less studied than tablets, differences in capsule formulations provided several classic examples of bioequivalence problems. The “Australian phenytoin incident” is one that resulted in disturbing clinical consequences.^[54] This occurred when the filler was changed from calcium sulfate to lactose, yielding higher plasma concentrations of a narrow-therapeutic-range drug that resulted in toxicity to many patients.

There are two main types of capsules: hard gelatin and soft gelatin (soft elastic). More research has examined the properties of hard capsules, which consists of a shell encapsulating powdered or granulated ingredient, which is often precompressed. The release properties are important because the gelatin itself dissolves rapidly (although there have been cross-linking problems^[55]).

Soft gel capsules have been useful as a delivery vehicle for drugs with solubility problems, such as lipophilic compounds. They can be dissolved in some cases in aqueous media with the aid of surfactants, but more usually in polyethylene glycol or oils.^b Formulation is critical because drugs can crystallize, and this has been a very recent problem with ritonavir.^c In drug release, the rupture or burst time of the capsule is the critical point for the dissolution of contents.

Tablets. As the most familiar and convenient of the dosage forms used by the consumer, the often complex formulation of tablets is not evident. However, it is possibly the most studied type of formulation, and there are many examples of bioavailability problems often detected by dissolution. Compression and disintegration are the major determinants of drug release from tablets, and they depend on the eventual release of smaller particles for dissolution.

In the past, sugar coating interfered with disintegration and dissolution; but, presently, coating is rarely problematic, except with some enteric-coated products.

Nonoral dosage. Reference has already been made to the formulation of parenteral, topical, and percutaneous skin and inhalation dosage forms. These range from simple solutions with little biopharmaceutical risk to highly complex drug-device systems for transdermal or metered-dose inhalation. Thorough biopharmaceutical evaluation is therefore an important part of product development.

Compendial Monograph Tests and Standards

As has been noted elsewhere, new drug applications involve setting standards and specifications that are acceptable to regulatory agencies but proprietary to the applicant. However, the ICH process in guideline Q6A^[27] is intended to “assist, to the extent possible, in the establishment of a single set of global specifications for new drug substances and new drug products.” The importance of pharmacopeial methods is promoted as follows:

Pharmacopeial Tests and Acceptance Criteria: References to certain methods are found in pharmacopoeias in each region. Wherever they are appropriate, pharmacopeial methods should be utilized. Whereas differences in pharmacopeial methods and/or acceptance criteria have existed among the regions, as harmonized specification is possible only if the methods and acceptance criteria defined are acceptable to regulatory authorities in all regions, this guideline is dependent on the successful completion of harmonisation of pharmacopeial methods for several attributes commonly considered in the specification for new drug substances or new drug products.

Among the tests that are “essentially harmonized” are dissolution and disintegration apparatuses, and there are efforts to agree on the media and acceptance criteria for those tests. However, it has been noted that the goal of 100% harmonization “would be unrealistic and unattainable.”^[56]

Although, clearly, quality control tests on finished product, as well as in-process controls, have bearing on the biopharmaceutical properties, e.g., content uniformity, the primary in vitro batch tests for biopharmaceutical quality are dissolution and disintegration and, when appropriate, particle size. Dissolution and disintegration have been applied to nonoral as well as oral tablet, capsule, and suspension formulations. Thus the British Pharmacopoeia (BP) has disintegration tests for suppositories and pessaries,^[57] and the USP has dissolution tests for transdermal patches^[58] and indomethacin suppositories.^[58]

Content uniformity. As with most pharmacopeial tests, there is no statistically designed sampling plan for the

^bMorton, F. Quoted by McGilveray, I.J. *Drug Inf J* **1996**, 30, 1029–1037.

^cAbbot Labs. Quoted in *Wall St. Journal*, July 28, **1998**, p. B5.

content uniformity test. Production lot units are to be tested, and the sample size is the same for large or small production runs. Good manufacturing practice expectations and shelf life derived from stability investigations will lead to increased sampling.

The USP has a statement on the lack of sampling plan and statistical advice with their standards. It is noted that “repeats, replicates, statistical rejection of outliers or extrapolation of results to larger populations are neither specified nor proscribed by the compendia.”^[58] However, with its legal status in the United States and Canada, any specimen tested as directed in a monograph, at any time before its date of expiry, shall comply. The tests are somewhat arbitrary in the use of statistics. As an example, the content uniformity tests for some articles, but not others, use relative standard deviations. On the other hand, some dissolution tests have tolerances based on single-unit test results, whereas others have pooled samples.

The USP Content Uniformity tests^[59] are to be applied to products containing 50 mg or less of active ingredient. For amounts above 50 mg, comprising 50% or more by weight of the dosage units, weight variation tests are substituted. For the content uniformity test, 30 units are chosen for testing, from which 10 individual units are first measured by appropriate assay. For tablets, suppositories, and suspensions, the individual unit amounts (% label claim) are obtained and the mean and standard deviation are calculated. If 10 units all lie within the range of 85–115% and the relative standard deviation is 6% or less, the batch is accepted. If 1 unit is outside the 85–115% range but is within 75–125%, then the further 20 units are tested. The second stage requires that no more than 1 unit in the 30 be outside the range 85–115% but not 75–125%. The relative standard deviation for the 30 shall be not more than 7.8%. (The BP test has the same 1 in 30 tolerance but no relative standard deviation.^[57])

For capsules, transdermal systems, and inhalants, the tolerance in the USP^[59] is met at stage 1 if 9 of the 10 units are within 85–115% and no unit is outside 75–125%, then stage 2 requires testing of the remaining 20 units. The stage 2 tolerance is that not more than 3 of the 30 units be outside the range of 85–115% and no unit outside 75–125%. The same relative standard deviation limits prevail as for tablets.

For metered-dose inhalers^[59] in the first stage, 10 units are allowed a wider tolerance of 75–125% and 1 unit up to the range 65–135%. In that case, if 2 or 3 units are outside the 75–125% range, a further 20 units are assayed and not more than 3 of the 30 are outside the 75–125% range; in addition, no unit is outside the 65–135% label claim. There are no relative standard deviation limits provided for this dosage form.

Particle size. This is an active substance test applied to relatively few drugs of limited aqueous solubility when

it has been determined to influence absorption from the final dosage form of the product. Griseofulvin is the classic example (USP). The decision tree II 3 in the ICH Q6A^[27] document is useful for this test with the first question: Is the particle size critical to dissolution solubility or bioavailability? If the answer is yes, criteria have to be developed. Unfortunately, different tests and apparatuses for specific surface area or particle size distribution are not directly comparable. The acceptance criteria are set based on the observed range of variation of three or more lots, taking into account the potential for particle growth. Acceptance criteria will include acceptable particle size distribution in terms of the percent of total particles in given size ranges. The mean, upper, and/or lower particle size limits should be well defined.

Aerosol droplet size and distribution. This is a variation of the drug powder, active substance test that defines the particle in its broadest sense^[30] to include primary drug particles and multiparticulate aggregates. In most of the USP aerosol monographs, particle size is measured, after some priming shots, by actuating the aerosol onto a microscope slide. Particles are examined under standard magnification and field conditions to ensure that most measure less than 5 μm long and to limit those over 10 μm . The USP^[58] also describes two single-stage impactor and one multistage impactor devices for measuring particle size distribution. These tests for respirable volume or dose are being introduced for better quality control of these devices. For salbutamol (albuterol in the United States) pressurized inhalation, the BP^[57] applies a twin-impinger device (one of the single-stage devices in the USP). The number of replicates is not stated, but not less than 35% of the average amount delivered per actuation is deposited in the lower impingement chamber.^[57] The European Pharmacopeia (EP) adopted the BP twin impinger as a general test for aerosols,^[60] and an adaptation has been proposed for nasal sprays.^[61]

Disintegration. The relationship between disintegration, which is a visual test, and dissolution, in which the amount of drug is measured, is complex. Since the 1970s, the USP has attempted to apply dissolution for as many as possible of its solid oral dosage form monographs and has expanded this to many nonoral formulations. In Europe, the issue of dissolution, as discussed by the BP,^[62] is limited to products for which bioavailability problems are more likely. This has led to ICH guideline Q6A, which states that “dissolution testing for immediate-release solid oral dosage products of very water-soluble drug substances may be replaced by disintegration testing.”^[27] It is apparent by comparing the USP and the BP that the former has many fewer monographs, which include a disintegration test, because generally it has been replaced by dissolution.

The disintegration apparatus for tablets and capsules is virtually identical in the United States,^[58] European,^[63]

and Japanese^[64] pharmacopeias. It is called the *basket rack assembly*, with six cells (tubes) held in place with two circular plastic plates and a wire mesh attached to the lower plate to retain particles above a certain size. For some tests, plastic disks are inserted such as pistons in the tubes. Water is the usual immersion fluid, but buffers are used in some monographs.

The set time for passing the visual endpoint test of complete disintegration varies with the monograph; in general, 30 min or less for uncoated tablets, sometimes longer for coated tablets, and with an “acid-resistance” time test for delayed release, enteric-coated tablets.

In stage 1 of the test (USP), six tablets are tested. If these are all disintegrated in the time stated in the monograph, the lot passes (again, there is no given sampling plan). If up to two tablets fail to disintegrate, then (stage 2) a further 12 tablets are tested and the lot passes only if no more than 2 of the 18 total fail to disintegrate completely (an 11% allowance for failure).

The test for buccal tablets allows 4 hr, with the same tolerance as just stated for tablets. For sublingual tablets, each monograph gives a time, but the acceptance criteria are as just stated for tablets.

For delayed-release (enteric-coated) tablets, there is a survival test for 1 hr in simulated gastric fluid. There is zero tolerance for failure among the six tablets, which should show no evidence of disintegration, cracking, or softening. The second part of the test is with simulated intestinal fluid buffer, when, according to the time in the individual monograph, the same acceptance criteria (all 6 in the first stage or 16 of 18 in the second stage) prevail as for tablets.

For capsules, whether hard or soft gelatin, there is a modification of the apparatus, with a removable wire mesh cloth being attached to the top (as well as the bottom) circular plates. The tolerances for all 6 to pass in stage 1 or 16–18 in stage 2 are the same as for tablets, according to the times in the individual monograph.

The BP describes a different apparatus used in Europe for suppositories and pessaries.^[63] Although the usual time is 30 min, for indomethacin, three suppositories are tested and weighed at 90 min when more than 75% must be dissolved.

Dissolution. This may be regarded as the most sensitive of the in vitro biopharmaceutical tests. It is regarded by the USP as a useful surrogate for in vivo bioequivalence.^[58] However, the FDA scale-up and postapproval changes guidelines^[14,65] apply dissolution for only minor changes of formulation, process, or equipment. Its use for bioequivalence comparisons between products is controversial. Nonetheless, it is the primary lot-to-lot quality control test for biopharmaceutical properties. Also, it is applied universally during the formulation development.

The apparatuses are described in the USP^[58] and the EP.^[63] However, because the EP does not include

monographs on specific dosage forms, the BP is an example of a European compendium with specific dissolution standards.

Conventional/Immediate Release. First introduced in the USP during the 1970s, with a modification of the disintegration apparatus just described, two major apparatuses are applied for the dissolution of conventional tablets and capsules, including those with coatings.^[58] These are apparatus 1, called the *rotating basket* method, in which a removable cylindrical wire mesh base is attached to a spindle, and apparatus 2, the *paddle* apparatus, in which a spindle is attached to a paddle. Both rotate in water, buffer, or other medium (according to individual monographs) held at 37 ± 0.5 °C. The volume is usually 900 ml; the stirring rate, usually 50 rpm (paddle) or 100 rpm (basket), is given in the individual monographs. Six cells are usually used in one assembly.

The test procedure involves a sampling plan similar to that for the disintegration tests, with sequential acceptance stages. Six tablets or capsules are tested first; if necessary, up to a total of 24 units may be tested. The pharmacopeias do not impose any other sampling plan but expect the acceptance criteria to be met with any sample from a lot.^[58]

For immediate- (conventional-) release units, the percentage of dose (label claim) to be dissolved (Q) and the time are stated in the individual monographs. The USP, however, for some time has had the acceptance standards shown in Table 1.^[58] There is no request for relative standard deviation or any other statistical manipulation.

The USP has recently introduced the pooled-sample tolerance for some products, avoiding individual assays.^[59] There is again a three-stage testing. The first stage is complete if the average for all 6 units (pooled sample) is not less than $Q + 10\%$. If necessary, the second stage, with another 6 units added, requires the pooled average to be equal or be more than $Q + 5\%$. Finally, if necessary, a further 12 units are tested, and the pooled average of the total 24 units must be equal or be more than Q .

Many manufacturers plot profiles of percent dissolved vs. time and SUPAC.MR^[14] has suggested a formula for comparison of profile f_2 , the similarity factor. Polli, Singh Rekhi, and Shah^[66] have discussed other methods for comparing dissolution profiles. However, these have rarely been validated as discriminating between lots of acceptable and unacceptable bioequivalence, and also they are arbitrary.

For delayed-release (enteric-coated) dosage forms, an acid (gastric fluid) survival test is applied before the conventional-release test for which the acceptance criteria (Table 1) are applied.^[58] The other type of modified-release dosage forms, extended release, is described shortly.

Dissolution of Semisolid Dosage Forms (such as Creams, Gels, Lotions, and Ointments). This in vitro release test is suggested in the SUPAC guideline for non-sterile semisolid dosage forms.^[67] The apparatus includes

Table 1 USP Dissolution Test Acceptance Criteria

Stage	Number tested	Acceptance criteria
S_1	6	Each unit is not less than $Q + 5\%$.
S_2	6	Average of 12 units ($S_1 + S_2$) is equal to or greater than Q , and no unit is less than $Q - 15\%$.
S_3	12	Average of 24 units ($S_1 + S_2 + S_3$) is equal to or greater than Q , not more than 2 units are less than $Q - 15\%$, and no unit is less than $Q - 25\%$.

S_1 —first stage; S_2 —second stage; S_3 —third stage.

an open-chamber diffusion cell (Franz cell) fitted with a synthetic membrane. Diffusion of drug from the topical product to and across the standard area of the membrane is obtained by sequential assay of samples taken from the receptor fluid over the appropriate time intervals, usually to 6 hr. Typically, six cells are tested, and there is a random distribution of test and reference (in this case, the changed formulation vs. the original). Usually, the drugs in the aliquots are quantitated by high-pressure liquid or gas-liquid chromatography.

Because the release of drug from a standard surface is proportional to the square root of time ($\sqrt{t}$), the results are plotted as the amount of drug measured per unit area ($\mu\text{g}/\text{cm}^2$) vs. $\sqrt{t}$, yielding a straight line. The slope of this line reflects the release rate and is formulation-specific. Changes of the slope can be used to monitor between-batch or between-formulation effects. Slopes should involve at least five sample times, and six replicates of each test (and reference) batch are recommended.

The results are obtained in a two-stage manner. In the first stage, six slopes each of test and reference release rates are obtained and a 90% confidence interval (90% CI) for the ratio of the median in vitro release for test and reference is computed. If this 90% CI falls within the limits of 75–133.33%, no further testing is necessary. If this tolerance is not met, 12 additional slopes are obtained for each product and the 90% CI is computed for the total of 18 slopes of each product (original 6 + 12 repeats). Computation from all results should yield a 90% CI of 75–133.33%. It is emphasized in the guideline^[67] that the in vitro release test is useful, with the following caveat:

However, at this time the evidence available for the in vitro: in vivo correlation of (the test) is not as convincing as that for in vitro dissolution as a surrogate for in vivo bioavailability of solid oral dosage forms. Its utility is limited to assess product “sameness” under certain limited scale-up and postapproval changes.

Dissolution of Transdermal Systems. Three apparatuses (5, 6, and 7) are described in the USP^[58] for measuring the release of drug for transdermal patches. They are also described in the EP.^[64] The general release standards suggested include three time points, in terms of the dosing interval D , expressed in hours.

Apparatus 5, “paddle over disk,” is a modification of the USP apparatus 2 (paddle) in which the patch is retained on the bottom of the vessel with a stainless steel disk.

Apparatus 6, “cylinder,” is a modification of USP apparatus 1 in which the rotating basket is replaced with a stainless steel cylinder stirring element, with the patch being retained within the cylinder.

In apparatus 7, “reciprocating disk,” a series of calibrated glass (or inert plastic) vials are set up in rows. The patch is attached to a sample holder that is then suspended from a vertically reciprocating shaker run at about 30 cycles/min. After a set time, the holder moves to the next row of calibrated vessels containing the dissolution medium. Samples are then obtained across time from the rows of calibrated vessels.

All the transdermal release media are kept at $32 \pm 0.5^\circ\text{C}$. The only patch described in the USP to which these release rate tests have been applied is nicotine, and it is product-specific, because all three apparatuses are applied. However, the standards differ for four products. One patch has stated limits of 35–75% in 1 hr, 55–95% in 2 hr, and not less than 73% in 4 hr. The other extreme is a patch set to deliver 31–87% in 2 hr, 62–191% in 12 hr, and 85–261% in 24 hr.

The tolerances are given, as with the immediate-release tablets and capsules, as a possible three-stage testing. Thus if six units are tested and all are within the stated ranges, no further testing is needed. If some units are outside the ranges, stage 2 is run, and of the total of 12 units, no individual value can be outside by more than 10%. If not more than 2 are outside the ranges, then a further 12 units are tested; not more than 2 of the total 24 units can be outside the stated ranges by more than 10%, and none can be outside the average of the stated range by more than 20%.

Release Tests for Extended-Release Articles. The two apparatuses, 1 and 2, just described in detail are applied to test the release from some extended-release products. However, usually the profile of the release of drug is obtained over the labeled dosage interval, usually 12 or 24 hr. A minimum of three time points is chosen to test the usual 6 (first stage) up to 24 (third stage) units. In general, an early time point test for not more than 20% of label to dissolve, a second (mid dosage interval) will check for 50–60% release, and a third sampling, toward the end of the dose interval, will test for 80% release. Tolerances are

established in the individual monographs for accepting or rejecting the profile.

In the USP, beyond apparatuses 1 and 2, two additional apparatuses are described for extended-release articles.^[58] These are the *reciprocating cylinder* and *flow-through* apparatuses. The four apparatuses may be used to develop in vitro/in vivo correlations, also described in the USP. A general tolerance table is provided for extended release, with the ranges being specified in each monograph.

BIOAVAILABILITY AND BIOEQUIVALENCE

Bioavailability and bioequivalence of drug products emerged as important attributes and have been applied to the regulation of medicines for about 25 yr. Bioequivalence was first used in the approval of generic products in Canada in the 1970s^[68] and was defined there in 1973.^[69] However, the publication in 1977^[2] of the U.S. regulations on bioavailability and bioequivalence was a landmark that led to abbreviated new drug applications, in which product efficacy is determined by bioequivalence to a reference listed product.

Definitions

Different authorities offer slight variations on the U.S. Federal Register definitions:^[2]

Bioavailability: The rate and extent to which the active drug ingredient or therapeutic ingredient is absorbed from a drug product and becomes available at the site of action.

Bioequivalent drug products: Pharmaceutically equivalent products that display comparable bioavailability when studied under similar experimental conditions.

Note: The rate and extent of absorption of the test drug do not show a significant difference from the rate and extent of absorption of the reference drug when administered at the same molar dose of the therapeutic ingredient under similar experimental conditions in either a single dose or multiple doses.

Bioavailability is a pharmacokinetic attribute of a drug that depends on absorption, distribution, metabolism, and excretion after administration. *Absolute bioavailability* refers to the comparison of oral with intravenous administration of a drug. Thus presystemic metabolism and first-pass metabolism can be distinguished from poor absorption properties. Drugs with poor absorption will show limited bioavailability. However, drugs that are completely absorbed can also demonstrate poor bioavailability because of the extensive metabolism of the parent. In the latter case, the oral dose shows only a fraction of the intravenous dose in plasma profiles.

Determination of Bioavailability and Bioequivalence

Determination of Bioavailability

Bioavailability is determined in humans after the administration of a drug by measuring the concentration of the active drug and its (major) metabolites in whole blood, plasma, or serum as a function of time after dosing. It can also be estimated by measurement of the amount of drug or its metabolites excreted in urine as a function of time. As just noted, absolute bioavailability is one such key study. Also, a study of the blood and urine profiles related to dose is required to examine dose proportionality (or disproportionality) or change in pharmacokinetic parameters with change in dose.^[1] Other bioavailability studies submitted in NDAs apply the bioequivalence model described next. These include comparison of the pharmaceutical alternatives, such as clinical trial capsule dose form of a drug with the to-be-marketed formulation, and, also, dosage-strength-equivalent studies to show that equivalent doses of different strengths deliver the same amount of drug (e.g., 3×100 mg vs. 1×300 mg tablets).^[1]

Determination of Bioequivalence

The 1992 amendments to the CFR^[70] provide the following in vivo and in vitro approaches, in descending order of accuracy, sensitivity, and reproducibility, for determining the bioequivalence of a drug product.

- 1a. An in vivo test in humans in which the concentration of the active ingredient or active moiety and its active metabolites, in whole blood, plasma, and serum, is measured as a function of time.
- 1b. An in vitro test that has been correlated with and is predictive of human in vivo bioavailability data.
- 1c. An in vivo test in animals that has been correlated with and is predictive of human bioavailability.
2. An in vivo test in humans in which the urinary excretion of the active moiety and its active metabolites are measured as a function of time.
3. An in vivo test in humans in which an appropriate acute pharmacologic effect of the active moiety and its active metabolites are measured as a function of time, if such an effect can be measured with sufficient accuracy, sensitivity, and reproducibility.
4. Appropriately designed comparative clinical trials, for the purposes of demonstrating bioequivalence.

In general, for drugs that are absorbed systematically, approach 1 is the expected study. With some products active against urinary tract infections, approach 2 might be acceptable. For inhalant dosage forms, such as bronchodilators, approach 3 has been applied. Clinical trials (approach 4) have been required for topical drug comparisons.

Design and Implementation of Bioequivalence Studies

Guidances on bioequivalence study design and implementation are available from the FDA on specific drugs. General guidelines are provided by Health Canada;^[71] these have also been described for the U.S. by Dighe and Adams.^[72]

The most common type of study for systematically available drugs is the randomized, single-dose crossover in healthy volunteers. Its major attributes include:

Crossover with a washout period.

A small number of healthy adults, usually 24–36 (12 or more in Canada).^[71]

Single doses of test and reference product.

Appropriate sampling of blood to measure: > 80% of total area under the time—plasma (blood) concentration curve (AUC).

Measures of AUC and peak plasma (blood) concentration ($C_{\max}$) examined by statistical procedures.

For cases *when urine is measured*, again, in healthy volunteers, samples are collected until 95% of the drug is eliminated based on half-life. Usually, urine is collected every 2 hr when a short half-life drug is administered, but this interval can lengthen to 6 hr if sampling extends to 2 days or more. The Canadian guideline^[71] indicates that > 40% of unchanged drug should be eliminated in urine. The amount of drug per sampling period and the cumulative amount of drug excreted are calculated. Also, the rate of excretion in urine is obtained.

For extended-release drugs and some drugs with non-proportional kinetics, *multiple-dose studies* are required:

Crossover.

Healthy volunteers (patients if necessary for ethical reasons).

Dosed to steady state, with a washout period between test and reference dosing.

Predose ($C_{\min}$) concentrations obtained daily.

At steady state, plasma concentrations are obtained to establish the profile of drug (and sometimes metabolites) over time from last dose.

Measures of AUC, $C_{\max}$, $C_{\min}$, and fluctuation are obtained and examined by statistical procedures.

For *pharmacodynamic evaluations of equivalence*, studies may be carried out in patients. An example is for albuterol.^[73] In the case of this bronchodilator, asthmatic patients with moderate disease were admitted to the study. Details of another pharmacodynamic bioequivalence test, the vasoconstrictor assay for topical corticosteroids, are given later.

Statistical Analysis of Bioequivalence Studies

The most comprehensive instructions for statistical analysis of bioequivalence studies are given in the Canadian

guidelines.^[71,74] However, Dighe and Adams^[72] also provide a full description of the U.S. FDA expectations.

Single-Dose Crossover Study

Analysis of variance (ANOVA) must include the randomization scheme for the design, where all subjects randomized into the study are included and identified by code, sequence, and dates of dosing periods for both test and reference.^[71]

The ANOVA should include the appropriate statistical tests of all effects in the model.

All the data for all subjects, including any “dropouts” with measured results, should be presented. Supplementary analysis may be carried out with excluded subjects or data points. Exclusion must be justified.

ANOVA should be carried out on $t_{\max}$ and λ (terminal slope) data and on the logarithmically (ln) transformed AUC_T and AUC_I and $C_{\max}$ data. (AUC_T is to be the last quantifiable point; AUC_I is to infinity).

Reported results should include means and CVs (across subjects) for each product.

The ANOVA containing source, degrees of freedom, sum of squares, mean square, F - and p -values, and the derived intrasubject and intersubject CVs.

Table 2 (from Ref. [71]) provides the ANOVA for the crossover design for ln (AUC_T) for a 16-subject study and derived CVs.

Table 3 provides the AUC ratio estimate, at a 90% confidence interval, showing how these were calculated. ($\bar{X}$ represents the geometric mean.)

Table 2 AUC_T (ng·hr/ml) Analysis—ANOVA for ln (AUC_T)

Source	df	SS	MS	F	PR > F
Seq	1	0.0535	0.0535	0.09	0.770
Subject (Seq)	14	8.4375	0.6027	8.26	< 0.001
Period	1	0.0241	0.0241	0.33	0.574
Form	1	0.1373	0.1373	1.88	0.192
Residual	14	1.0211	0.0729	—	—

Intrasubject CV = $100 \times (\text{MS Residual})^{0.5} / 2 = 100 \times (0.0729)^{0.5} / 2 = 27\%$.

Intersubject CV = $100 \times (\text{MS Subject (Seq)} - \text{MS Residual} / 2)^{0.5} / 2 = 100 \times (0.6027 - 0.0729 / 2)^{0.5} / 2 = 51\%$.

(From Ref. [71].)

Table 3 AUC_T (ng·hr/ml) Analysis—Calculations

Difference = Test $\bar{X}$ – Reference $\bar{X}$ = 5.39 – 5.52 = – 0.13
$SE_{\text{Difference}} = (2MS_{\text{Residual}}/n)^{0.5} = (2 \times 0.0729/16)^{0.5} = 0.0955$
AUC ratio = $100 \times e^{\text{Difference}} = 100 \times e^{(-0.13)} = 88\%$
90% Confidence limits:
Lower, Upper = $100 \times e^{(\text{Difference} \pm t_{0.05,14} \times SE_{\text{Difference}})}$
Lower = $100 \times e^{(-0.13 - 1.761 \times 0.0955)} = 74\%$
Upper = $100 \times e^{(0.13 - 1.761 \times 0.0955)} = 104\%$

The standards for bioequivalence in the U.S. require that the 90% confidence interval for test product vs. reference (innovator) product for AUC and $C_{\max}$ be within the limits of 0.8 and 1.25 (or 80% and 125%). In Canada, only the AUC is required to be within this interval (for uncomplicated drugs) and the $C_{\max}$ ratio only (no confidence interval) within 80–125%.

Multiple-Dose Studies

Again, the Canadian guideline for modified release^[74] provides details from multiple-dose comparisons. Similar to single-dose analysis, information on the ANOVA randomization and sequence is required. The difference is in the number of variables to be listed and tested:

Analysis of $t_{\max}$, λ , and fluctuation = $(C_{\max} - C_{\min})/(AUC_{\tau}) \times 100\%$ should be carried out on the raw scale, while calculations for AUC_{τ} (over dosage interval), AUC_{τ} , and AUC_{τ} , $C_{\max}$ should use the logarithmic (ln) scale. The 90% confidence interval about the mean AUC_{τ} , $C_{\min}$, $C_{\max}$, and fluctuation parameters should be provided.

Table 4 gives the ANOVA for the crossover design model for ln (AUC_{τ}). This analysis gives the appropriate intrasubject variance estimate, MS (Residual), for the calculation of the 90% confidence interval. Any significant effects in the model, other than Subject (Seq), should be investigated. The intrasubject and intersubject CVs should also be calculated.

The AUC_{τ} ratio estimate and its 90% confidence interval are derived in the calculations shown in Table 5 ($\bar{X}$ refers to geometric means). If this study had a balanced design (i.e., an equal number of subjects per sequence), the

Table 4 AUC_{τ} ($\mu\text{g}\cdot\text{hr}/\text{ml}$) Analysis—ANOVA for ln (AUC_{τ})

Source	df	SS	MS	F	PR > F
Seq	1	0.44521	0.44521	1.6849	0.21525
	14	3.69921	0.26423	12.4240	0.00001
	1	0.02422	0.02422	1.1389	0.30394
	1	0.00405	0.00405	0.1905	0.66917
	14	0.29775	0.02127	—	—

Intrasubject CV = $100 \times (\text{MS}_{\text{Residual}})^{0.5} = 100 \times (0.0213)^{0.5} = 15\%$.

Table 5 AUC_{τ} ($\mu\text{g}\cdot\text{hr}/\text{ml}$) Analysis—Calculations

Difference = Test $\bar{X}$ – Reference $\bar{X}$ = 8.0768 – 8.0992 = –0.0225
$SE_{\text{Difference}} = 0.0516$
AUC_{τ} ratio = $100 \times e^{\text{Difference}} = 100 \times e^{-0.0225} = 98\%$
90% Confidence limits:
Lower, Upper = $100 \times e^{(\text{Difference} \pm t_{0.025,14} \times SE_{\text{Difference}})}$
Lower = $100 \times e^{(-0.0225 - 1.761 \times 0.0516)} = 89\%$
Upper = $100 \times e^{(0.0225 + 1.761 \times 0.0516)} = 107\%$

difference would simply be the difference in the arithmetic means of the ln (AUC)s. Because of the fact that the study was not balanced, the least-squares mean estimate for each formulation is used to form this difference, together with the appropriate standard error.

The standards for bioequivalence (U.S.) are that AUC_{τ} , $C_{\max}$, and $C_{\min}$ 90% confidence intervals for test vs. reference (innovator) product be within the limits of 0.8 and 1.25 (80–125%). In Canada, for $C_{\max}$ and $C_{\min}$ only, ratios are required to be within 80–125% and the AUC within the 90% confidence limits.

Food-Effect Bioavailability and Bioequivalence Studies

The presence of food in the gastrointestinal tract about the time of drug administration can affect absorption and other bioavailability measures for many drugs and drug products. Most regulatory authorities require the food challenge information for any new extended-release product because the dose-release mechanism may be either enhanced or impaired by food. This is particularly true of mechanisms influenced by the change of pH in moving down the gut. Karim^[75] presented an excellent paper, providing several decision trees that discussed the importance of food effect studies early in drug development. The FDA-proposed guidance,^[76] in fact, describes the factors Karim discussed.

Both the U.S. and Canadian guidelines^[74] for extended-release dosage forms require single-dose studies of food effects for the approval of new products. Generally, a high-fat meal would be given in one leg of a study and the volunteers would be fasted in the other leg. In the case of a generic extended-release product, the study could be a four-way crossover of test and reference, both with and without food.

In the Canadian guidelines, there is no limit for bioavailability because clinical trials will be provided for a new drug or for a first-entry modified release. However, the food challenge is informational for labeling.

Also, in the case of “dose-dumping,” the product may not be accepted. In the Canadian guidelines for bioequivalence, the product is expected to meet the standards for single-dose studies with and without food, i.e., AUC_{τ} 90% confidence interval of test vs. reference within the range 80–125%, $C_{\max}$ mean ratio from 80% to 125%.

The U.S. draft guidelines of December 1997 examine the food effects in much more detail.^[76] An important section in these guidelines discusses when food effect studies (in bioavailability/bioequivalence) may not be important and covers some “diagnostic factors” to determine whether additional studies of food effect are important. For a drug, such factors include:

High solubility across the intended dose range.

High permeability across the intended dose range (e.g., oral absorption > 90%).

Minimal or no effect of inactive ingredients or absorption of the drug substance in the fasted state (i.e., equivalent profiles in vivo of solution or suspension and test formulation).

For a drug product, the factors include:

Rapidly dissolving drug product.

In vitro dissolution characteristics similar in different pH media and rotation speeds in USP apparatuses 1 and 2.

If all of these factors are positive, absence of a food effect study may be justified. If they are not all positive, then the sponsor must provide justification concerning why a food effect study is not important.

The general design for both BA and BE studies in the draft U.S. guidelines^[76] is the randomized, balanced, single-dose, two-treatment, two-period, and two-sequence crossover. The reference for the bioavailability study of a new drug at the Investigational New Drug stage would be solution or suspension, and this would be tested with and without food to show whether the drug substance is affected. In the preapproval phase, if the drug substance is affected greatly by food, the proposed marketing formulation should also be tested with and without food. For bioequivalence of a substantially changed formulation or a generic, the test formulation and the reference listed drug (or original formulation) should be tested in the presence of food.

The U.S.-proposed guidelines^[74] suggest that the decision documenting whether a food effect is absent or not be based on the ratio of means (population geometric means, based on log-transformed data) of fed and fasted treatments. It is absent if:

AUC, 90% CI fall within 80–125%.

$C_{\max}$, 90% CI fall within 70–143%.

A food effect is concluded when either or both the AUC and $C_{\max}$, 90% CI are found to be outside the given ranges, and the sponsor is asked to indicate the clinical relevance of the magnitude of the observed data.

The Canadian modified-release (MR) guidelines^[74] require only that the AUC in food effect studies be within 80–125% and that, as for fasted studies, the $C_{\max}$ ratio be within 80–125%.

It is of interest that both the BioInternational meetings in 1992^[77] and 1996^[78] had conference statements on the determination of food effects. In the latter, it was noted that the ethnic differences in food are less important in the determination of such effects than caloric content and protein, carbohydrate, and fat ratio (kCal distribution).

Narrow-Therapeutic-Range Drugs in Canada

For drugs designated to be of narrow therapeutic range, bioequivalence requirements are tightened in the Narrow

Therapeutic Range (NTR) guidelines. Thus 95% confidence intervals are imposed and, for both AUC and $C_{\max}$ in fasted and fed conditions, should have test vs. reference means (ln) with 95% CI within 80–125%.^[79]

Individual Bioequivalence

Currently, new guidelines for individual bioequivalence are under review.^[80,81] Studies will involve replicate design, i.e., two treatments of test and two of reference formulation.^[82] This will allow an estimate of intrasubject variation (subject-by-formulation interaction). It is evident that the statistics are complicated^[83] and will involve more assumptions than current regulatory models for bioequivalence. It may lead to improved standards for NTR drugs and a means to deal with highly variable drugs, especially if some scaling factor can be agreed upon.

Pharmacodynamic Measures of Bioequivalence

The U.S. CFR^[2] and EU guidelines on bioavailability and bioequivalence allow the use of pharmacodynamic (PD) comparisons to show the equivalence of products. Other uses of pharmacodynamics involve surrogate endpoints for efficacy, such as blood pressure reduction and CD4 cell counts, and also for investigating the relationship between pharmacokinetic and pharmacodynamic variables. This section will discuss the use of PD in bioequivalence. Examples of PD use in bioequivalence include dermatologic corticosteroids^[84] and albuterol metered-dose inhalers.^[73] The FDA guidelines on corticosteroids^[84] provide great detail on setup and interpretation of studies, and the albuterol studies were discussed at an FDA Advisory Committee meeting in August 1996, where some information was made available.^[73]

The corticosteroid guidelines provide information on the use of the Stoughton–McKenzie vasoconstrictor bioassay^[85] for the assessment of topical corticosteroids. The approach relies on the effect of corticosteroids, which produce vasoconstriction, resulting in blanching of the skin. This is presumed to relate to the amount of drug entering the skin.

The method involves the application of a corticosteroid skin preparation (ointment, cream, or lotion) to skin (forearm) of healthy human subjects, where it is left for 6–18 hr. The vasoconstriction (blanching) of the skin is then monitored by a trained, blinded observer who notes the degree of blanching using a visual rating scale (either 0–3 or 0–4) at the single time point after removal of the formulation (2 hr is common). Chromameter readings of the blanching may offer a more objective assessment than the human observer.^[84]

The key problem of pharmacodynamic studies is that the dose response reaches an asymptote, or effect saturation, and this may be within the range of the application

dose. It is therefore important to identify the linear dose response region. Also, some subjects are more sensitive in showing effects than others; that is, responders have to be differentiated from nonresponders. The FDA recognizes this, and therefore studies to validate the method and choose responders, “pilot studies,” define the pivotal study dose duration on the vasoconstriction assay:

$$E = E_0 + \frac{E_{\max} D}{E_{\max} + D}$$

where E = effect, E_0 = baseline effect, $E_{\max}$ = maximal effect, ED_{50} = half-maximal effect, and dose D is the dose at which the effect is half maximal. The pilot study seeks to establish ED_{50} , D , and D_2 , which are the doses approximately one half and two times ED_{50} , respectively. The values bracket ED_{50} , corresponding to approximately 33% and 67% of maximal response, and they are in the sensitive portion of the dose duration–response curve. Responders are those who provide visual scale readings above 1 on a scale of 0 to 3 or 4.

The data are obtained by chromameter or visual observation and are corrected for baseline value at the site; and, from the individual points on the area under the effect curve, Area Under Effect Curve (AUEC) is measured, such as from 0 to 24 hr. The model is fit by using all the observations of individual subjects to provide ED_{50} and $E_{\max}$ values pooled from the 12 subjects.

The dose-duration information, such as $ED_{50} = 2$ hr, $D_1 = 1$ hr, and $D_2 = 4$ hr, is taken from this pilot study (based on the reference product values) to apply to up to 60 volunteers in the pivotal study to compare test product with reference. As well as using the ED_{50} from the pilot study, within-study day replicates are applied to volunteers, and individual dose-duration responses are obtained. The D_1/D_2 ratios of individual AUEC values obtained are accepted only if they exceed 1.25; values below this designate the volunteer as a “nondetector.” Only “responders” and “detectors” are used in the comparisons of dosage forms.

The data treatment from the study includes only responders, but results from “nondetectors” must be reported.

The AUEC of, say, 0–24 hr is computed for each baseline-adjusted, untreated control, site-corrected dose duration.

“Detectors” are identified from individual subjects whose AUEC values for D_1 and D_2 are both negative (responder) and meet the dose-duration response criterion of 1.25, i.e.,

$$\frac{\text{AUEC at } D_2}{\text{AUEC at } D_1} \geq 1.25$$

where $\text{AUEC at } D_2 = 0.5(\text{AUEC at } D_{2 \text{ left arm}} + \text{AUEC at } D_{2 \text{ right arm}})$ and $\text{AUEC at } D_1 = 0.5(\text{AUEC at } D_{1 \text{ left arm}} + \text{AUEC at } D_{1 \text{ right arm}})$. Only subjects with complete data sets, i.e., duplicated values of D_1 and D_2 and quadruplicate values of test, reference, and untreated, should be included in the data analysis.

All data from all subjects, however, including nondetectors, should be reported (nonresponders would have been eliminated because this is a subject exclusion criterion).

The statistical analysis can be applied only to untransformed results because although AUEC values are usually negative, some are positive. The presence of positive and negative values prevents the use of conventional statistical transformations. Confidence intervals are calculated for Locke’s exact confidence interval method.

The 90% confidence interval is obtained from the ratio of the AUEC response from test to that of reference. Both of the AUEC figures are averages of four replicates. The example from the guidelines given next shows that only 7 of the 12 volunteers were found to be “detectors” (Table 6).

The calculation of the 90% confidence interval for the data set from 7 to 12 subjects from the FDA guidelines (Chapter 1046) is given here. The data used to calculate the confidence interval are the average AUEC values of “detectors” (evaluable subjects) only. The calculation of the confidence interval is facilitated by the calculation of the following intermediate quantities:

$$\bar{X}_T = \frac{1}{n} \sum_{i=1}^n X_{Ti} \quad \bar{X}_R = \frac{1}{n} \sum_{i=1}^n X_{Ri}$$

where n is the number of evaluable subjects, 7 in this example.

Table 6 Average AUEC Values for Subjects Meeting the Dose Duration–Response Criterion $D_2/D_1 \geq 1.25$

Subject	AUEC _(0–24) test product (average)	AUEC _(0–24) reference product (average)
2	– 48.52	– 22.20
3	– 38.99	– 18.65
4	– 7.62	– 22.42
7	0.98	– 10.96
9	– 32.05	– 37.40
11	– 26.18	– 26.73
12	– 11.62	– 12.56

$$\hat{\sigma}_{\text{TT}} = \frac{\sum_{i=1}^n (X_{\text{Ti}} - \bar{X}_{\text{T}})^2}{n-1} \quad \hat{\sigma}_{\text{RR}} = \frac{\sum_{i=1}^n (X_{\text{Ri}} - \bar{X}_{\text{R}})^2}{n-1}$$

$$\hat{\sigma}_{\text{TR}} = \frac{\sum_{i=1}^n (X_{\text{Ti}} - \bar{X}_{\text{T}})(X_{\text{Ri}} - \bar{X}_{\text{R}})}{n-1}$$

These are the sample means, sample variances, and sample covariance for the individual evaluable subject average AUEC data. For the example, these are

$$\bar{X}_{\text{T}} = -23.43 \quad \bar{X}_{\text{R}} = -21.56$$

$$\hat{\sigma}_{\text{TT}} = 323.13 \quad \hat{\sigma}_{\text{RR}} = 80.10 \quad \hat{\sigma}_{\text{TR}} = 78.83$$

We define t as the 95th percentile of the t -distribution for $n - 1$ degrees of freedom. For example, for $n = 7$, t (6 degrees of freedom) is 1.9432. Now we define

$$G = \frac{t^2 \hat{\sigma}_{\text{RR}}}{n \hat{X}_{\text{R}}^2}$$

$G < 1$ is required to have a proper confidence interval. If $G \geq 1$, the study does *not* meet the in vivo bioequivalence requirements. In the example, $G = 0.0930$.

Under the assumption that $G < 1$, we calculate

$$K = \left(\frac{\bar{X}_{\text{T}}}{\bar{X}_{\text{R}}} \right)^2 + \frac{\hat{\sigma}_{\text{TT}}}{\hat{\sigma}_{\text{RR}}} (1 - G) + \frac{\hat{\sigma}_{\text{TR}}}{\hat{\sigma}_{\text{RR}}} \left(G \frac{\hat{\sigma}_{\text{TR}}}{\hat{\sigma}_{\text{RR}}} - 2 \frac{\bar{X}_{\text{T}}}{\bar{X}_{\text{R}}} \right)$$

In the example, $K = 2.791$.

The confidence interval limits may now be calculated:

$$\frac{\left(\frac{\bar{X}_{\text{T}}}{\bar{X}_{\text{R}}} - G \frac{\hat{\sigma}_{\text{TR}}}{\hat{\sigma}_{\text{RR}}} \right) \mp \frac{t}{\bar{X}_{\text{R}}} \sqrt{\frac{\hat{\sigma}_{\text{RR}}}{n} K}}{1 - G}$$

In the example, 90% confidence interval limits are 53.6% and 165.9%, based on the data of 7 evaluable subjects.

The corticosteroid guidelines^[84] state that “the Office of Generic Drugs has not determined at this time (June 1995) the equivalence interval for bioequivalence. The Office requires that an equivalence interval wider than 80–125%, as a public standard, may be necessary.” In fact, this was recognized in the albuterol discussion of the Pharmaceutical Sciences Advisory Committee,^[73] which recommended 70–143% as an acceptable 90% CI for these particular pharmacodynamic response studies (bronchoprovocation).

There is another set of topical skin products guidelines^[86] that advocates dermatopharmacokinetic measurements in place of clinical trials. The statistical calculations are identical to those for AUC, C_{max} , etc. under the preceding immediate-release bioequivalence studies, as is the 90% confidence interval width of 80–125%.

DEVELOPMENT, SCALE-UP, AND POSTAPPROVAL CHANGES, AND IN VITRO (DISSOLUTION)/IN VIVO (PLASMA CONCENTRATION PROFILE) CORRELATIONS

Introduction

The preceding sections have documented, with some examples, the in vitro properties that may influence the biopharmaceutical performance of drugs. It has been noted that solubility, permeability, and rate of dissolution are key properties of the drug substance, and that the dissolution behavior is the key property of the solid dosage form in leading to consistency of in vivo performance as measured by bioavailability or bioequivalence studies. During new drug or new product development (either by changes by innovator or toward introduction of a generic), there will be attempts to minimize expensive in vivo studies with intensive in vitro evaluation. Possibly, some pilot developmental bioequivalence studies will be completed before choosing the pivotal batch for bioequivalence. Such information is helpful in designing specifications (Q6A)^[27] and can also assist in decisions postapproval.

With the SUPAC guidelines, the FDA has attempted to formalize decisions on postapproval changes. The Europeans give much less detail in their guidelines on variations,^[85] but they approach the same problems.

Scale-Up and Postapproval Changes Guidelines

Common Elements

The three SUPAC guidelines issued—immediate-release solid oral dosage forms (SUPAC-IR),^[14] modified-release solid oral dosage forms (SUPAC-MR),^[65] and nonsterile semisolid dosage forms (SUPAC-SS)^[67]—contain some common features as well as advice specific to the dosage-form type. Some common features are:

Currently relates only to scale-up and postapproval changes. (However, principles may be applied to other preapproval situations.)

Level of changes defined—subgroups:

Components and composition.

Site of manufacture.

Batch size (scale-up or scale-down).

Manufacturing equipment.

Manufacturing process.

Each level of change, as well as being defined, has sections listing:

Test documentation comprising:

Chemistry.

Dissolution.

Bioequivalence.

Filing documentation, which includes all stability information.

Changes in components and composition. Level 1. These are changes that are unlikely to have any detectable impact on formulation quality and performance.

Level 2. These are changes that could have a significant impact on formulation quality and performance.

Level 3. These are changes that are likely to have a significant impact on formulation quality and performance.

Changes in site of manufacture. Level 1. These changes consist of site changes within the same facility, but with no changes in:

Manufacturing, components, or composition scale-up.

Equipment.

Standard operating procedures.

Environmental conditions and controls.

Personnel.

Manufacturing batch records.

Level 2. These changes consist of site changes within a contiguous campus or between facilities in adjacent city blocks. There are no other changes—see Level 1.

Level 3. These changes consist of changing the manufacturing site to a different campus. Except for personnel, no other change should be made, as in Level 1.

Changes in batch size (scale-up/scale-down). Level 1 includes changes up to and including a factor of 10 times the size of the pilot/biobatch. However,

Equipment used is of the same design and operating principles.

It is manufactured in full compliance with good manufacturing practices.

Same standard operating procedures and controls are used in the original and changed batches.

Equipment changes. Level 1. These include changes from nonautomated or nonmechanical to automated or mechanical equipment and to alternative equipment of the same design and operating principle.

Level 2. These include changes in equipment to different design and operating principles.

There is an equipment addendum for SUPAC-IR with more details.

Process changes. Level 1. These are changes such as rate of mixing, mixing times, operating speeds, and holding times within the approved application ranges.

Level 2. These are process changes as in Level 1 but outside approved application ranges.

Level 3. These are changes in the type of process used in the manufacture of the product, such as a change from wet granulation to direct compression of powder. Level 3 changes are not expected in the SUPAC-SS category.^[59]

Test documentation. For biopharmaceutical properties in SUPAC, the major decisions in testing concern which situations require bioequivalence studies. Thus the degree of change requires a hierarchy of dissolution studies; when the change is considered likely to have an impact on performance, a study of bioequivalence will be expected between the change batch and the original.

Level 1 changes for IR and MR products will not require additional dissolution studies, except for those in the approved application or in the USP for the particular article. In general, Level 3 changes demand a single-dose bioequivalence comparison of original and changed batches.

Dissolution tests in the IR document^[14] are described in three “cases” of increasing complexity, A, B, and C.

Case A. This uses USP apparatus 1 at 100 rpm, or apparatus 2 at 50 rpm, with 900 ml of 0.1N hydrochloric acid. The units should meet the Q value of 85% in 15 min according to the USP table of tolerances for dissolution.^[58] If changed and original batches meet this standard, it is acceptable.

Case B. This involves a multipoint dissolution profile in the apparatus (1 or 2) and medium in the application or the compendial conditions (if the article is listed), with samples taken at 15, 30, 45, 60, and 120 min or until an asymptote is reached. Profiles of changed and originals are compared using the f_2 equation (see the upcoming section on “Comparison of Profiles”).

Case C. Five separate dissolution profiles are obtained in water, 0.1N hydrochloric acid, and in USP buffer media at pH 4.5, 6.5, and 7.5, with sampling times at 15, 30, 45, 60, and 120 min or until an asymptote is reached. The original and changed batch profiles are compared with the f_2 statistic. If it can be justified, a surfactant can be added to the media to generate the profiles.

SUPAC-IR

The biopharmaceutical drug classification system^[12] is used in SUPAC-IR, and for Level 2 changes in composition for highly soluble, highly permeable drugs, the dissolution case A is applied. If this fails, cases B and C dissolution should be performed. For low-permeability drugs with high solubility, a multipoint dissolution (case B) should be applied. For low-solubility, high-permeability

drugs, case C should be applied. Comparisons should use the f_2 formula. For Level 3 changes in composition, case B dissolution is applied, but an in vivo bioequivalence study is also required unless there is an in vivo/in vitro correlation.

In SUPAC-IR, changes of site Level 3, batch size Level 2, and process Levels 2 and 3, the case B dissolution profile comparison is suggested. If the changes show similarity of dissolution, bioequivalence comparisons are required only for Level 3 changes in composition and process. As well as preapproval, it is likely that these principles of similarity and use of the biopharmaceutical drug classification system will extend to preapproval changes. Bioequivalence studies may be waived when in vitro/in vivo correlations have been established.

SUPAC-MR

The SUPAC-MR application of dissolution requires, for Level 1 change, that dissolution should be compared only by using the method in the approved application or in the USP (if the article is listed). For all Level 2 changes (composition, site, batch size, equipment, and process), extensive dissolution comparison is required. For extended release, for example, in addition to application or compendial release testing, the multipoint dissolution profiles should be obtained in three other media. These may include (but are not restricted to) water, 0.1N hydrochloric acid, and pH 4.5 and 6.8 buffer. Sampling times should be appropriate, such as 1, 2, and 4 hr and every 2 hr until either 80% of the drug is released or an asymptote is reached.

For delayed release (enteric-coated) as well as an acid survival (0.1N hydrochloric acid for 2 hr), multipoint dissolution profiles are to be obtained at three different agitation speeds in buffer at pH 4.5–7.5.

Bioequivalence studies are required in the absence of an in vitro/in vivo correlation for Level 3 changes in composition, site, and manufacturing process; this will be accepted with a single-dose study.

SUPAC-SS

For the SUPAC-SS category of product, dissolution is also considered useful, and has been described in "Dissolution." Levels 2 and 3 changes in composition or manufacturing site and Level 2 changes in equipment, process, or batch size require comparison of drug release slopes.

Comparison of Profiles

The comparison of dissolution is considered important not only for any impact on SUPAC decisions, but also for setting specifications as noted in both the FDA dissolution guidelines^[88] and in the ICH Q6A "specifications" document.^[27] The guidance on dissolution^[79] has a section on comparison of dissolution profiles that describes the similarity factor, f_2 ,

used in some decisions for SUPAC-IR and SUPAC-MR when profiles are being compared. This calculates the percentage difference between the two profiles at each time point and, with an error term, provides a measure of similarity in the percent dissolution. It is a logarithmic reciprocal, square root transformation of the sum of the squared error expressed as:

$$f_2 = 50 \log \left\{ \left[1 + \left(\frac{1}{n} \right) \sum_{t=1}^n (R_t - T_t)^2 \right]^{-0.5} \right\} \times 100$$

where n is the number of time points, R_t is the dissolution value of the reference (prechange batch in SUPAC) at time t , and T_t is the dissolution value of the test (change) batch at time t . Dissolution profiles of 12 units are obtained, such as with a biobatch (R) and a production lot (T), and the f_2 factor is calculated. Values for f_2 above 50 indicate a sameness of the two curves and suggest that the performance of the two batches will be similar.

The dissolution guidelines discuss other comparison procedures, including model-independent multivariate and model-dependent procedures. These have also been discussed by Polli, Singh Rekhi, and Shah.^[66]

In Vitro/In Vivo Correlations

Dissolution, as has already been described in several earlier sections, is a key biopharmaceutical test, and it is widely applied as a quality control test for finished products. However, its discriminating power is significantly enhanced if an in vitro/in vivo correlation can be established such that the dissolution behavior can predict bioavailability and discriminate between acceptable and inequivalent batches. For highly water-soluble drug classes (high-solubility, high-permeability and high-solubility, low-permeability) when the rate-determining step for absorption is not dissolution, correlations are unlikely. However, for low-solubility, high-permeability drugs, correlations are possible. Also, for extended-release drug products, in which the formulation is used to control the release of active drug, correlations are expected. This expectation is formalized in the USP (Chapter 1088)^[58] as well as the EU^[89] and FDA (SUPAC) modified-release guidelines. It also emerges in the ICH specifications document.^[27]

Levels of Correlation

Three correlation levels are defined, in decreasing order of usefulness, for predicting absorption behavior. The relationship in which the in vitro profile reflects the entire plasma drug-concentration profile resulting from the administration of the given drug product is most useful.^[58]

Level A correlation. This represents a point-to-point relationship between dissolution and the in vivo input rate

of the drug from the administered drug batch. The curves may be directly superimposable or depend on a constant offset value. There are different means of calculating the in vivo input rate curve, and, increasingly, mathematical deconvolution is being applied. The correlation is validated by in vitro and in vivo testing extremes of the formulation [slow, intermediate (intended for production), and fast dissolution test batches] with dissolution and from pilot bioavailability studies. A solution or immediate-release product is also given. This allows the differential determination of input curves from solution and sustained-release product to compare with the dissolution curve to provide a point-to-point correlation. The two extremes and the production lots can be used to set specifications and also in justifying postapproval changes. Thus if a change provides a dissolution profile similar to that of the original (within the validated boundaries), the predicted bioavailability will also be expected to be similar.

Level B correlation. This uses the statistical moment analysis. The mean in vitro dissolution time is compared with the mean residence time or the mean in vivo dissolution time calculated from time-plasma concentration profiles. However, because the *shape* of the in vivo curve is not defined from mean residence time, it is less reliable for setting specifications.

Level C correlation. Because this relates only one dissolution time point, such as time for 50% to be dissolved, to one bioavailability variable, such as AUC, $C_{\max}$, or $t_{\max}$, it is of limited value. It is a single-point correlation and does not define the complete shape of the plasma level profile, and it cannot be used in predicting in vivo performance.

CONCLUSIONS

The essential features of biopharmaceutical characterization and testing of drug substances and products during development have been described here. From the earliest point after discovery, pharmaceutical development has focused on providing the optimum dose in the optimum time to the patient in a consistent manner. Thus it is multidisciplinary, including the study of the physicochemical attributes of the substance and the likely dosage form, the pharmacokinetic behavior in animals and humans, and the relationships to pharmacologic and clinical effects. The regulatory authorities are required to assess the development as part of safety and efficacy monitoring and to ensure that valid quality tests and specifications are appropriate to provide consistent product performance. Whereas much research has characterized the biopharmaceutics of solid oral dosage forms, the future challenge is to investigate further other types of dosage forms to assist in the management of preapproval and postapproval changes.

Biosimilar Studies: Sample Size

Seung-Ho Kang

Department of Applied Statistics, Yonsei University, Seoul, South Korea

Abstract

The two-arm equivalence parallel design has been widely utilized to assess the degree of biosimilarity between a biological product and a reference product. The aim is to show that the difference between two population means of a primary end point is less than a prespecified equivalence margin. A well-known sample size formula for the equivalence trial is expressed as follows:

$$n_1 = kn_2, n_2 = \frac{(z_{\alpha} + z_{\beta/2})^2 \sigma^2}{(\delta - |\mu_T - \mu_R|)^2} (1 + 1/k)$$

where n_1 and μ_T (n_2 and μ_R) are the sample size and the population mean of the primary end point of the biosimilar (reference) group, respectively. σ^2 , δ , and k are the population variance, the equivalence margin, and the sample allocation ratio, respectively. z_{α} is the upper alpha quantile of the standard normal distribution. It is known that this sample size formula is very conservative at times because the formula is derived based on the approximate power rather than the exact power. The exact power based on the sample size computed from the formula to have power of $1 - \beta$ is, in fact, $1 - \beta/2$ under certain conditions. Calculating the sample size precisely and numerically based on the exact power is recommended.

Keywords: Equivalence trial; Margin; Power.

INTRODUCTION

Due to the expiring patents of biological products, the development of generic versions of innovator biologic products has been the subject of increased attention in both biopharmaceutical industry and regulatory agencies.^[1] Sponsors should demonstrate high degrees of similarity in terms of the quality, efficacy, and safety between a biosimilar product and an innovator's biological product in order to obtain approval from the relevant regulatory agencies. In the development of a biosimilar product, a stepwise approach is usually recommended.^[2] A phase III comparative study is usually required in the last step of the stepwise approach, if there are uncertainties about the biosimilarity of the two products based on quality studies and non-clinical studies. Equivalence trials based on the two-arm parallel design are commonly used as phase III comparative studies during the development of biosimilar products.

One of the important issues when designing phase III comparative studies is the calculation of the sample

size. For economic, ethical, and scientific reasons, it is especially important not to overestimate sample sizes.

THE EQUIVALENCE TRIALS BASED ON THE TWO-ARM PARALLEL DESIGN

Although several measures and designs have been studied to evaluate the degree of biosimilarity between a biosimilar product and an innovator's biological product,^[3–7] the most widely used method involves a comparison of two population means based on the two-arm parallel design. Therefore, equivalence trials are frequently used in order to show that the difference between two population means of a primary end point is smaller than a prespecified equivalence margin. For example, the U.S. Food and Drug Administration draft guidance describes the importance of the equivalence trial, as given below:^[2]

A study employing a two-sided test in which the null hypothesis is that either (1) the proposed product is inferior

to the reference product or (2) the proposed product is superior to the reference product based on a pre-specified equivalence margin is the most straightforward study design for accomplishing this objective.

Similarly, the World Health Organization (WHO) guideline also emphasizes the importance of the equivalence trial, as follows:^[8]

Equivalence trials are strongly recommended for medicinal products with a narrow safety margin, such as insulin, to ensure that the SBP (biosimilar product) is not less and not more effective than the RBP (renovator biological product).

In equivalence trials based on the two-arm parallel design, patients are randomized into two groups—the patients in the first group receive a biosimilar product and the patients in the second group receive a reference product. The hypotheses of interest are given by:

$$H_0: |\mu_T - \mu_R| \geq \delta \text{ versus } H_a: |\mu_T - \mu_R| < \delta \quad (1)$$

where $\delta(>0)$ is a prespecified equivalence margin and μ_T and μ_R are the population mean of the primary end point in the biosimilar group and in the reference group, respectively.

THE EXACT AND APPROXIMATE POWER

Let $X_{T,i} (i=1, \dots, n_1)$ and $X_{R,i} (i=1, \dots, n_2)$ represent the continuous primary end points from the biosimilar product in the first group and the reference product in the second group, respectively, which independently follow a normal distribution with means of μ_T and μ_R and a common variance of σ^2 . The common variance σ^2 is assumed to be known for the calculation of the sample size. The hypotheses in Eq. 1 can be decomposed into two one-sided hypotheses, as follows.

$$H_{01}: \mu_T - \mu_R \leq -\delta \text{ versus } H_{a1}: \mu_T - \mu_R > -\delta \quad (2)$$

and

$$H_{02}: \mu_T - \mu_R \geq \delta \text{ versus } H_{a2}: \mu_T - \mu_R < \delta \quad (3)$$

If both H_{01} and H_{02} are rejected at the significance level of α , it can be concluded that H_0 in Eq. 1 is rejected at the significance level of α . Additionally, the two products are claimed to be biosimilar.

Both H_{01} and H_{02} are rejected at the significance level of α , if,

$$Z_L < -z_\alpha \text{ and } Z_U > z_\alpha \quad (4)$$

where

$$Z_L = \frac{\bar{X}_T - \bar{X}_R - \delta}{\sigma \sqrt{1/n_1 + 1/n_2}} \text{ and } Z_U = \frac{\bar{X}_T - \bar{X}_R + \delta}{\sigma \sqrt{1/n_1 + 1/n_2}} \quad (5)$$

where $\bar{X}_T$ and $\bar{X}_R$ are the sample means of the primary end point in the first and the second group, respectively.

Under the alternative hypothesis $H_a: |\mu_T - \mu_R| < \delta$, Kang and Kim^[9] showed that the power of this test is expressed as follows:

$$\begin{aligned} &P(Z_L < -z_\alpha \text{ and } Z_U > z_\alpha | H_a) \\ &= P(Z_L < -z_\alpha | H_a) + P(Z_U > z_\alpha | H_a) \\ &\quad - P(Z_L < -z_\alpha \text{ or } Z_U > z_\alpha | H_a) \end{aligned} \quad (6)$$

$$\geq 2\psi\left(\frac{\delta - |\mu_T - \mu_R|}{\sigma \sqrt{1/n_1 + 1/n_2}} - z_\alpha\right) - 1 \quad (7)$$

Here, ψ is the cumulative distribution function of the standard normal distribution. Note that Eq. 6 provides the exact power, whereas Eq. 7 gives the approximate power. If the sample size is calculated based on the approximate power with Eq. 7, we obtain the following well-known sample size calculation formula for the equivalence trials.^[10]

$$n_1 = kn_2 \text{ and } n_2 = \frac{(z_\alpha + z_{\beta/2})^2 \sigma^2}{(\delta - |\mu_T - \mu_R|)^2} (1 + 1/k) \quad (8)$$

where z_α is the upper alpha quantile of the standard normal distribution (e.g., $z_{0.05} = 1.645$), σ^2 is the population variance of the primary end point, k is the allocation ratio, and n_1 and n_2 are the corresponding sample sizes of the first group and the second group, respectively.

COMPARISON OF THE EXACT AND THE APPROXIMATE POWER

Kang and Kim^[9] compared the exact and the approximate powers based on Eqs. 6 and 7 with the following results.

1. The sample size calculation based on Eq. 8 is very conservative, necessitating larger sample sizes that are actually needed.
2. The exact power based on the sample size calculated by Eq. 8 for power of $1 - \beta$ is actually $1 - \beta/2$ under certain conditions.^[9] In other words, if the sample size is computed from Eq. 8 to have 80% power, the exact power with an identical sample size is, in fact, 90% in many practical cases.

The R code used to calculate the sample sizes based on both the exact and the approximate power level in each case is provided by Kang and Kim.^[9]

CONCLUSION

Although the well-known sample size calculation formula for the equivalence trials is simple, it has been found that the formula is very conservative. For example, in many practical cases, the sample sizes to achieve 80% power based on the approximate power actually produce 90% of the exact power. Therefore, calculating the sample size based on the exact power is recommended. Kang, Jung, and Baik^[11] compared the exact and the approximate powers in the binary end point and reached a similar conclusion.

Biosimilar Studies: Three-Arm Design

Seung-Ho Kang

Department of Applied Statistics, Yonsei University, Seoul, South Korea

Abstract

One of the most commonly used designs for assessing the degree of biosimilarity between a biosimilar product and a reference product is the two-arm parallel design, with which biosimilarity is assessed using the difference between two population means. A problem with this method is that the variability of a reference product among different batches cannot be taken into account accurately. This problem is overcome when using the three-arm parallel design, in which one arm is used for the biosimilar product and the other two arms are for the reference product. A relative distance is employed to evaluate the degree of biosimilarity. The distance between the biosimilar product and the reference product, defined as the absolute mean difference between the two products, becomes the numerator of the relative distance. The distance between the reference products from two different batches becomes the denominator of the relative distance. If the relative distance is less than a pre-specified margin, the two products are claimed to be biosimilar. Statistical tests based on a ratio estimator method were developed to assess the degree of biosimilarity when using the relative distance in the three-arm parallel design.

Keywords: Similarity; Biosimilar; Parallel design; Ratio estimator.

INTRODUCTION

As patents of biological products expire, evaluations of the degree of biosimilarity for these products to meet regulatory approval have received considerable attention. Many studies have been devoted to the search for a feasible biosimilarity criterion and its corresponding measurement technique.^[1–11] In practice, the two-arm-balanced parallel design has been widely utilized to assess the biosimilarity between a biological product and a reference product. In this design, biosimilarity is evaluated with an equivalence test whose hypotheses are given by:

$$\begin{aligned} H_0 : \mu_T - \mu_R \leq -\delta \text{ or } \mu_T - \mu_R \geq \delta \text{ versus} \\ H_A : -\delta < \mu_T - \mu_R < \delta \end{aligned} \quad (1)$$

where $\delta (\delta > 0)$ is a prespecified equivalence margin and μ_T and μ_R are the population means of the biological product and the reference product, respectively. Biosimilarity is assessed using the difference between the two population means. However, it is known that: 1) biosimilar products are generally very sensitive to environmental factors such as light and temperature differences; and 2) a small change at any critical stage of the manufacturing process could cause major changes in clinical outcomes. When the reference products come from two different manufacturing processes (locations) or from different batches from the same manufacturing process, the two-arm parallel design cannot feasibly incorporate the variability

of the reference products. Hence, when the equivalence margin in the two-arm parallel design is larger than the variability of the reference product, this method may arrive at the erroneous conclusion that the two products are biosimilar, although they are, in fact, considerably different. This problem can be resolved if the equivalence margin can be determined by considering the variability of the reference product before any clinical trial begins. However, in practice, this solution may not be feasible, as the variability of a reference product may not be known a priori. In order to solve this problem, the three-arm parallel design was proposed by Kang and Chow^[7] to assess the degree of biosimilarity between a biological product and a reference product.

THREE-ARM PARALLEL DESIGN

We consider three treatments: a biosimilar product (T) and two reference products from different batches (R_1 , R_2). In total, n patients are randomized into the following three groups. First, n_1 patients are assigned to the first group, to receive the biosimilar product T. The patients who are assigned to the second and third groups receive reference products R_1 and R_2 , respectively, with the number of patients in each group denoted by n_2 . The randomization ratio 2:1:1 is used with $n_1 = 2n_2$, and the total sample size is $N = n_1 + 2n_2$. Let Y denote a primary continuous response variable. If the two-arm parallel design is used, it

is possible to divide the reference arm randomly into two groups, R_1 and R_2 .

It is also necessary to define certain distances. Let $d(T, R)$ represents the distance between the biosimilar product T and the reference product R . Similarly, the distance between R_1 and R_2 is denoted by $d(R_1, R_2)$. There exist many possible candidates for specific forms of distance. Examples include:

$$d_1(T, R) = |\mu_T - \mu_R| \quad (2)$$

$$d_2(T, R) = |\mu_T / \mu_R| \quad (3)$$

$$d_3(T, R) = (\mu_T - \mu_R)^2 \quad (4)$$

$$d_4(T, R) = E(Y_T - Y_R)^2 \quad (5)$$

where μ_T is the population mean of Y for the patients with the biosimilar product T and μ_R is defined as $(\mu_{R_1} + \mu_{R_2})/2$, where μ_{R_1} and μ_{R_2} represent the population means of Y in patients who receive reference product R_1 and R_2 , respectively.

Kang and Chow^[7] considered what is known as the relative distance, as defined below, to evaluate the degree of biosimilarity between a biosimilar product and a reference product.

$$rd = \frac{d(T, R)}{d(R_1, R_2)} \quad (6)$$

Note that, because the distance values are non-negative, the relative distances are also non-negative. If the value of the relative distance rd is smaller than a prespecified margin δ ($\delta > 0$) in the three-arm parallel design, the two products are claimed to be a biosimilar. Therefore, the hypotheses for assessing biosimilarity are expressed as:

$$H_0 : rd \geq \delta \text{ versus } H_A : rd < \delta \quad (7)$$

Kang and Chow^[7] employed the absolute mean difference $d_1(T, R) = |\mu_T - \mu_R|$ to evaluate the biosimilarity between two products. We assume that $\mu_{R_1} \neq \mu_{R_2}$, as two different batches of the reference product cannot be completely identical. The relative distance is expressed as:

$$rd = \frac{|\mu_T - \mu_R|}{|\mu_{R_1} - \mu_{R_2}|} = \frac{|\mu_T - (\mu_{R_1} + \mu_{R_2})/2|}{|\mu_{R_1} - \mu_{R_2}|} \quad (8)$$

Hence, the hypotheses in Eq. 7 can be rewritten as:

$$H_0 : \theta \leq -\delta \text{ or } \theta \geq \delta \text{ versus } H_A : -\delta < \theta < \delta \quad (9)$$

where,

$$\theta = \frac{\mu_T - (\mu_{R_1} + \mu_{R_2})/2}{\mu_{R_1} - \mu_{R_2}} \quad (10)$$

The hypotheses in Eq. 9 can be decomposed into two one-sided hypotheses, as follows:

$$H_{01} : \theta \leq -\delta \text{ versus } H_{A1} : -\delta < \theta \quad (11)$$

and

$$H_{02} : \theta \geq \delta \text{ versus } H_{A2} : \theta < \delta \quad (12)$$

STATISTICAL TESTS FOR BIOSIMILARITY

Kang and Chow^[7] proposed two statistical tests in order to test the hypotheses in Eqs. 11 and 12. These were a test based on a ratio estimator and a linearization method. Here, we describe only the statistical test based on the ratio estimator because it has greater power than the linearization method.^[7]

Let $Y_{T,i}$ ($i = 1, 2, \dots, n_1$) and $Y_{R_{k,i}}$ ($k = 1, 2, i = 1, 2, \dots, n_2$) represent the response variables from the biosimilar product in the first group and the reference product in the second and third groups, respectively, with $n_1 = 2n_2$. We assume that $Y_{T,i}$ and $Y_{R_{k,i}}$ ($k = 1, 2$) follow independently normal distributions with means of μ_T and μ_{R_k} ($k = 1, 2$) and common variances of σ^2 . We also assume that the sample size is large enough such that the central limit theorem can be used. Kang and Chow^[7] constructed the following test statistic based on the ratio estimator.

$$\hat{\theta} = \frac{\bar{V}}{\bar{U}} = \frac{\bar{Y}_T - (\bar{Y}_{R_1} + \bar{Y}_{R_2})/2}{\bar{Y}_{R_1} - \bar{Y}_{R_2}} \quad (13)$$

where,

$$\bar{Y}_T = \frac{1}{n_1} \sum_{i=1}^{n_1} Y_{T,i} \quad (14)$$

$$\bar{Y}_{R_k} = \frac{1}{n_2} \sum_{i=1}^{n_2} Y_{R_{k,i}} \quad \text{for } k = 1, 2 \quad (15)$$

They also showed the asymptotic normality of $\sqrt{n_1}(\hat{\theta} - \theta)$.

$$\sqrt{n_1}(\hat{\theta} - \theta) \xrightarrow{d} N\left(0, \frac{2\sigma^2}{\mu^2} + 4 \frac{v^2}{\mu^4} \sigma^2\right) \quad (16)$$

where,

$$\mu = \mu_{R_1} - \mu_{R_2} \quad (17)$$

$$v = \mu_T - \frac{(\mu_{R_1} + \mu_{R_2})}{2} \quad (18)$$

The null hypothesis H_{01} in Eq. 11 is rejected if $Z_1 > z_{\alpha}$, where,

$$Z_1 = \frac{\hat{\theta} + \delta}{\frac{s}{\sqrt{n_1}} \sqrt{\frac{2}{(\bar{U})^2} + 4 \frac{(\bar{V})^2}{(\bar{U})^4}}} = \frac{\bar{V} / \bar{U} + \delta}{\frac{s}{\sqrt{n_1}} \sqrt{\frac{2}{(\bar{U})^2} + 4 \frac{(\bar{V})^2}{(\bar{U})^4}}} \quad (19)$$

and z_α is the upper α quantile of the standard normal distribution (e.g., $z_{0.05} = 1.645$) and

$$s^2 = \frac{\left[\sum_{i=1}^{n_1} (Y_{T,i} - \bar{Y}_T)^2 + \sum_{i=1}^{n_2} (Y_{R_1,i} - \bar{Y}_{R_1})^2 + \sum_{i=1}^{n_2} (Y_{R_2,i} - \bar{Y}_{R_2})^2 \right]}{(n_1 + 2n_2 - 3)} \quad (20)$$

Similarly, the null hypothesis H_{02} in Eq. 12 is rejected if $Z_2 < -z_\alpha$ where,

$$Z_2 = \frac{\bar{V} / \bar{U} - \delta}{\frac{s}{\sqrt{n_1}} \sqrt{\frac{2}{(\bar{U})^2} + 4 \frac{(\bar{V})^2}{(\bar{U})^4}}} \quad (21)$$

If each null hypothesis in both Eqs. 11 and 12 is rejected at the significance level of α , the two products are claimed to be biosimilar.

Kang and Chow^[7] derived the asymptotic power function of the statistical test based on the ratio estimator and calculated sample sizes numerically. Simulation studies also showed that the statistical test based on the ratio estimator keeps the empirical type I error rates under the nominal level.

BINARY END POINTS

The statistical test based on the ratio estimator in the three-arm parallel design was extended to three popular metrics for the binary end point—the risk difference, the log relative risk, and the log odds ratio.^[10] Let X_T and X_{R_i} denote the number of events of interest. It is assumed that:

$$X_T \sim B(n_1, p_T) \quad X_{R_i} \sim B(n_2, p_{R_i}), i = 1, 2 \quad (22)$$

and that the three random variables are independent. For the risk difference, the hypotheses used to assess the degree of biosimilarity are expressed as:

$$H_0^d : \theta_d \leq -\delta_d \text{ or } \theta_d \geq \delta_d \text{ versus } H_A^d : -\delta_d < \theta_d < \delta_d \quad (23)$$

where,

$$\theta_d = \frac{p_T - \frac{1}{2}p_{R_1} - \frac{1}{2}p_{R_2}}{p_{R_1} - p_{R_2}} \quad (24)$$

For the log relative risk, the hypotheses for assessing biosimilarity can be written as:

$$H_0^r : \theta_r \leq -\delta_r \text{ or } \theta_r \geq \delta_r \text{ versus } H_A^r : -\delta_r < \theta_r < \delta_r \quad (25)$$

where,

$$\theta_r = \frac{\log(p_T) - \frac{1}{2}\log(p_{R_1}) - \frac{1}{2}\log(p_{R_2})}{\log(p_{R_1}) - \log(p_{R_2})} \quad (26)$$

For the log odds ratio, the hypotheses of assessing biosimilarity can be given by:

$$H_0^o : \theta_o \leq -\delta_o \text{ or } \theta_o \geq \delta_o \text{ versus } H_A^o : -\delta_o < \theta_o < \delta_o \quad (27)$$

where,

$$\theta_o = \frac{\log\left(\frac{p_T}{1-p_T}\right) - \frac{1}{2}\log\left(\frac{p_{R_1}}{1-p_{R_1}}\right) - \frac{1}{2}\log\left(\frac{p_{R_2}}{1-p_{R_2}}\right)}{\log\left(\frac{p_{R_1}}{1-p_{R_1}}\right) - \log\left(\frac{p_{R_2}}{1-p_{R_2}}\right)} \quad (28)$$

Shin and Kang^[10] developed the three statistical tests for evaluating biosimilarity based on the asymptotic normality of $\sqrt{n_1}(\hat{\theta}_d - \theta_d)$, $\sqrt{n_1}(\hat{\theta}_r - \theta_r)$, and $\sqrt{n_1}(\hat{\theta}_o - \theta_o)$.

CONCLUSION

The three-arm parallel design consists of three arms—one arm is for the test product and the other two arms are for reference products from different batches. This design allows us to assess the relative distance in terms of the ratio of the difference between T and R and the difference between R_1 and R_2 . An advantage of the three-arm parallel design is that it uses the relative distance rather than the absolute difference in order to assess the degree of biosimilarity. Kang and Shin^[8] extended the three-arm parallel design to what is known as the $(k+1)$ -arm parallel design for cases in which $k \geq 3$.

Abstract

In recent years, the assessment of biosimilarity between a proposed biosimilar product and an innovative biological product has attracted much attention since the passage of the Biologics Price Competition and Innovation Act in 2009. In this article, we provide an overview of regulatory requirements for review and approval of biosimilar products. Unlike the generic products, the development of biosimilar products is much more complicated because of fundamental differences in functional structures and manufacturing processes. As a result, the criteria and standard methods for the design and analysis of bioequivalence assessment of generic drug products may not be directly applicable to assessing biosimilarity of biosimilar products. In this article, we provide some scientific/statistical considerations for criteria, design, and analysis regarding the assessment of biosimilarity and drug interchangeability of biosimilar products. In addition, we discuss scientific and practical issues raised at the 2010 Food and Drug Administration (FDA) public hearing and the 2011 FDA public meeting on biosimilar products.

Keywords: Biosimilar; Biosimilarity index; Highly similar; Stepwise approach; Totality of the evidence.

INTRODUCTION

Biological drugs make up one of the fastest growing sectors of the pharmaceutical and biotechnology industry (MIDAS, 2010). For example, in 2000, global biologics spending on biosimilars is expected to roar to \$190 billion (see, e.g., Fig. 1). This has given the pharmaceutical and biotechnology industry the opportunity for the development of biosimilars when the innovative biologics are going off patent protection.

Due to the high costs involved in the production and consumption of many drug products, regulatory regimes have been created to balance the intellectual property interests (patent protection) and investment made by innovative (originator) companies, with the need for wider patient access through generic forms of the drugs. In the United States (US), for the traditional chemical (small-molecule) drug market, such a regime was created by the Hatch-Waxman Act. The Hatch-Waxman Act added section 505(j) to the US Federal Food, Drug, and Cosmetic Act. This section and its accompanying regulations created the Abbreviated New Drug Application process, which was designed to provide independent generic firms with a strong incentive to develop and introduce lower cost generic drugs to consumers. By virtually all accounts, the

Hatch-Waxman Act has been extremely successful in bringing cheaper generic products to the market while maintaining incentives for the development and discovery of new drugs. Because of the effectiveness of the Hatch-Waxman Act approach in the context of traditional small-molecule drugs, some have called for applying a similar regime for biologics, given the high costs in this class of drugs. In particular, Rep. Henry Waxman (D-Cal.), one of the original authors of the Hatch-Waxman Act has sponsored the Access to Life-Saving Medicine Act to determine whether such a legal infrastructure was appropriate for regulating the follow-on biologics, and a thorough policy assessment was necessary. This effort has led to the passage of the Biologics Price Competition and Innovation (BPCI) Act.

Following the passage of the BPCI Act, the US Food and Drug Administration (FDA) hosted a public hearing between November 2 and 3, 2010, to obtain public input regarding scientific factors for assessing biosimilarity and drug interchangeability of biosimilar products. After extensive discussions, the FDA developed and circulated three draft guidances on biosimilars on February 9, 2012, and hosted another public hearing to obtain public input and comments on the draft guidances on May 11, 2012.^[1–3] At this Public Hearing, special attention was directed to the discussion of drug interchangeability in terms of the

Fig. 1 Global spending on biologics

concepts of switching and alternating as described in the BPCI Act. On March 23, 2010, the BPCI Act (as part of the Affordable Care Act) was written into law, which has given the FDA the authority to approve similar biological drug products. After additional discussions, the draft guidances were finalized in early 2015.

As indicated in the BPCI Act, a biosimilar product is defined as a product that is *highly similar* to the reference product notwithstanding minor differences in clinically inactive components, and there are no clinically meaningful differences in terms of safety, purity, and potency. However, little or no discussion regarding how similar is considered highly similar is given in the BPCI Act.^[4,5] On the other hand, the European Union (EU) has a well-established and well-documented legal and regulatory pathway for the review and approval of biosimilars. Other countries and organizations around the world, including Australia, Canada, China, Japan, and Switzerland, and the World Health Organization (WHO), are also following the same scientific principles for an abbreviated approval pathway for biosimilars. In contrast, the US is at the very beginning of the process, with a legal pathway being discussed by the US Congress for a number of years. The FDA's views on biosimilars can be examined from a publication^[6] and from communications between the FDA and the Congress. These documents seem to indicate that FDA is contemplating similar scientific principles to those established by the EU European Medicines Agency (EMA).

The purpose of this article is to provide a comprehensive review of regulatory requirements, criteria for biosimilarity, statistical methods including power calculations for the determination of sample size that is needed for the assessment of biosimilarity between a proposed biosimilar

product and an innovative biologic product. In addition, a unified approach for demonstrating biosimilarity using the concept of reproducibility is introduced.

REGULATORY REQUIREMENTS

For the assessment of similar biologic products, regulatory requirements from the WHO and different regions such as the EU, the US, and the Asia-Pacific Region such as Japan, Taiwan, South Korea, and China are similar and yet slightly different (Wang and Chow 2012),^[7–11] which are briefly described below. In order to provide a better understanding of regulatory requirements from different regions, a comparison of requirements for the evaluation of biosimilars is given in [Table 1](#).

World Health Organization

As an increasingly wide range of similar biotherapeutic products (SBPs) was under development or already licensed in many countries, WHO formally recognized the need for the guidance for their evaluation and overall regulation in 2007. The *Guidelines on Evaluation of Similar Biotherapeutic Products (SBPs)* were developed and adopted by the 60th meeting of the WHO Expert Committee on Biological Standardization in 2009.^[12] The intention of the guidelines was to provide globally acceptable principles for licensing biotherapeutic products that were claimed to be similar to the reference products that had been licensed based on a full licensing dossier. The scope of the guidelines includes well-established and well-characterized biotherapeutic products that have been

Table 1 Comparison of regulatory requirements

	WHO	Canada	Korea	EU	Japan
Term	SBPs	SEBs	Biosimilars	Biosimilars	Follow-on biologics
Scope		Recombinant protein drugs		Mainly recombinant protein drugs	Recombinant protein drugs
Efficacy	Double-blind or observer-blind; equivalence or non-inferiority design		Equivalence design	Comparability margins should be prespecified and justified	
Reference Product	Authorized in a jurisdiction with a well-established regulatory framework			Authorized in the EU	Authorized in Japan
Stability	1. Accelerated degradation studies 2. Studies under various stress conditions				Not necessary
Purity	Process-related and product-related impurities				
Manufacture	1. Same standards required by the NRA for originator products 2. Full chemistry and manufacture data package				
Physicochemical	1. Primary and higher order structure 2. Posttranslational modifications				
Biological activity	1. Qualitative measure of the function 2. Quantitative measure (e.g., enzyme assays or binding assays)				
Nonclinical studies	1. <i>In vitro</i> (e.g., receptor-binding, cell-based assays) 2. <i>In vivo</i> (PD activity, at least one repeat dose toxicity study, antibody measurements, local tolerance)				
Safety	Pre-licensing safety data and risk management plan				
Principles	1. Generic approach is not appropriate for follow-on biologic 2. Follow-on biologic should be similar to the reference in terms of quality, safety, and efficacy 3. Stepwise comparability approach: Similarity of the SBP to RBP in terms of quality is a prerequisite for reduction of nonclinical and clinical data required for approval 4. Case-by-case approach for different classes of products 5. Pharmacovigilance is stressed				
PK study design and criteria	1. Single-dose, steady-state studies, or repeated determination of PK 2. Crossover or parallel 3. Include absorption and elimination characteristics 4. Traditional 80%–125% equivalence range is used				
PD	PD markers should be selected and comparative PK/PD studies may be appropriate				

marketed for a suitable period of time with proven quality, efficacy, and safety, such as recombinant DNA-derived therapeutic proteins.

Key Principles and Basic Concept

As indicated in the WHO guidelines, one of the most important principles of developing an SBP is the stepwise approach starting with the characterization of quality attributes of the product and followed by nonclinical and clinical evaluations. Manufacturers should submit a full-quality dossier that includes a complete characterization of the product, the demonstration of consistent and robust manufacture of their product, and the comparability exercise between the SBP and the reference biotherapeutic product (RBP) in the quality part, which together serve as the basis for the possible reduction in data requirements in the nonclinical and clinical development. This principle indicates that the data reduction is only possible for the nonclinical and clinical parts of the development program,

and significant differences between the SBP and the chosen RBP detected during the comparability exercise would result in requirement for more extensive nonclinical and clinical data. In addition, the amount of nonclinical and clinical data considered necessary also depends on the class of products, which calls for a case-by-case approach for different classes of products.

Reference Biotherapeutic Product

The choice of the RBP is another important issue covered in the WHO guidelines. Traditionally, National Regulatory Authorities (NRAs) have required the use of a nationally licensed reference product for registering generic medicines, but this may not be feasible in countries lacking nationally licensed RBPs. Thus, additional criteria may be needed to guide the acceptability of using an RBP licensed in other jurisdictions. Considering the choice of the RBP, WHO requires that it should have been marketed for a *suitable* duration and have a volume of marketed use, and be

licensed based on full-quality, safety, and efficacy data. Besides, the same RBP should be used throughout the development of SBP, and the drug substance, dosage form, and route of administration of the SBP should be the same as those of the RBP.

Quality

As mentioned in the preceding section, the comprehensive comparison showing quality similarity between SBP and RBP is a prerequisite for applying the clinical safety and efficacy profile of RBP to SBP; thus, a full-quality dossier for both drug substance and drug product is always required. To evaluate comparability, WHO recommends the manufacturer to conduct a comprehensive physicochemical and biological characterization of the SBP in head-to-head comparisons with RBP. The following aspects of product quality and heterogeneity should be assessed.

Manufacturing Process

The manufacturing process should meet the same standards as required by NRAs for the originator products, and implement Good Manufacturing Practices, modern quality control and assurance procedures, in-process controls, and process validation. The SBP manufacturer should assemble all available knowledge of the RBP with regard to the type of host cell, formulation, and container closure system, and submit a complete description and data package delineating the whole manufacturing process including obtaining target genes and their expression, the optimization and fermentation of gene engineering cells, the clarification and purification of the products, the formulation and testing, aseptic filling, and packaging.

Characterization

Thorough characterization and comparability exercise are required, and details should be provided on the primary and higher order structure, posttranslational modifications, biological activity, process- and product-related impurities, the relevant immunochemical properties, and results from accelerated degradation studies and studies under various stress conditions.

Nonclinical and Clinical Studies

After demonstrating the similarity of SBP and RBP in quality, the proving of safety and efficacy of an SBP usually requires further nonclinical and clinical data. Nonclinical evaluations should be undertaken both *in vitro* (e.g., receptor-binding studies, cell proliferation, cytotoxicity assays) and *in vivo* (e.g., biological/pharmacodynamics (PD) activity, repeat dose toxicity study, toxicokinetic measurements, anti-product antibody titers,

cross-reactivity with homologous endogenous proteins, neutralizing capacity of the product).

In terms of the clinical evaluation, the comparability exercise should begin with pharmacokinetic (PK) and PD studies followed by the pivotal clinical trials. PK studies should be designed to enable detection of potential differences between SBP and RBP. Single-dose, crossover PK studies in a homogeneous population are recommended by WHO. The manufacturer should justify the choice of single-dose studies, steady-state studies, or repeated determination of PK parameters, and the study population. Due to the lack of established acceptance criteria for the demonstration of similar PK between SBP and RBP, the traditional 80%–125% equivalence range is often used. Besides, PD studies and confirmatory PK/PD studies may be appropriate if there are clinically relevant PD markers. In addition, similar efficacy of SBP and RBP has to be demonstrated in randomized and well-controlled clinical trials that should preferably be double-blind or at least observer-blind. In principle, equivalence designs (requiring lower and upper comparability margins) are clearly preferred for the comparison of efficacy and safety of SBP with RBP. Non-inferiority designs (requiring only one margin) may be considered if appropriately justified. WHO also suggest the pre-licensing safety data and the immunogenicity data should be obtained from the comparative efficacy trials.

In addition to the nonclinical and clinical data, applicants also need to present an ongoing risk management and pharmacovigilance plan, since data from preauthorized clinical studies are usually too limited to identify all potential side effects of the SBP. The safety specification should describe the important identified or potential safety issues for the RBP, and any that are specific for the SBP.

In summary, the WHO guidelines on evaluating SBPs represent an important step forward in the global harmonization of biosimilar product evaluation and regulation, and provide a clear guidance for both regulatory bodies and the pharmaceutical industry.

The EU

The EU has pioneered the development of a regulatory system for biosimilar products. The EMA began formal consideration of scientific issues presented by biosimilar products at least as early as January 2001 when an *ad hoc* working group discussed the comparability of medicinal products containing biotechnology-derived proteins as active substances.^[13] In 2003, the European Commission amended the provisions of EU secondary legislation governing requirements for marketing authorization of applications for medicinal products to establish a new category of applications for “similar biological medicinal products”.^[14] In 2005, the EMA issued a general guideline in order to introduce the concept of similar biological medicinal products, to outline the basic principles to

be applied, and to provide applicants with a “user guide,” showing where to find relevant scientific information.^[15] Since then, 14 biosimilar products have been approved by EMA under the pathway. One of the rejected biosimilars is Alpheon (interferon alfa-2a). It was developed by BioPartners GmbH and designed to become a biosimilar of the reference product Roferon-A for the treatment of adult patients with chronic hepatitis C. The EMA refused the marketing authorization for Alpheon due to the difference identified between Alpheon and the reference product, such as impurities, stability, and side effects.

Key Principles and Basic Concept

Unlike WHO’s guideline, which seems to focus more on recombinant DNA-derived therapeutic proteins, EMA’s guidelines clearly indicate that the concept of a “similar biological medicinal product” is applicable to a broad spectrum of products ranging from biotechnology-derived therapeutic proteins to vaccines, blood-derived products, monoclonal antibodies, gene and cell therapy, and so on. However, comparability exercises to demonstrate similarity are more likely to be applied to highly purified products that can be thoroughly characterized such as biotechnology-derived medicinal products. Considering the amount of data submitted, EMA also requires a full-quality dossier, while the comparability exercise at the quality level may allow a reduction of the nonclinical and clinical data requirement compared to a full dossier. In 2011, EMA published a concept paper on the revision of the guideline on similar biological medicinal products.^[16] It emphasizes another main concept that clinical benefit has already been established by the reference medicinal product, and that the aim of a biosimilar development program is to establish similarity to the reference product, not clinical benefit. Besides, a clear definition of “biosimilar,” the feasibility to follow the generic legal basis for some biological products, and the refinement based on the experience gained are recommended.

Reference Biotherapeutic Product

Similar to the regulatory requirement from WHO, EMA requires that the active substance, the pharmaceutical form, the strength, and the route of administration of the biosimilar product be the same as those of the reference product. The same chosen reference medicinal product should be used throughout the comparability program for quality, safety, and efficacy studies during the development of the biosimilar product. One of the major differences between WHO and EMA in terms of the choice of the reference product is that EMA requires the chosen reference medicinal product to be a medicinal product authorized in the community. Data generated from comparability studies with medicinal products authorized outside the community may only provide supportive information.

Quality

In 2006, the Guideline on Similar Biological Medicinal Products Containing Biotechnology-Derived Proteins as Active Substance: Quality Issues was adopted by the Committee for Medicinal Products for Human Use (CHMP),^[17] which addresses the requirements regarding manufacturing processes, the comparability exercises for quality, analytical methods, physicochemical characterization, biological activity, purity, and specifications of the similar biological medicinal product. In 2011, EMA issued a concept paper on the revision of this guideline.^[18] This concept paper proposes that the guideline published in 2006 needs refinements taking account of the evolution of quality profile during the product life cycle, since in the context of a biotherapeutic product claiming or claimed to be similar to another one already marketed, the conclusion of a comparability exercise performed with a reference product at a given time may not hold true from the initial development of the biosimilar product, through marketing authorization, until the product’s discontinuation.

Nonclinical and Clinical Evaluation

The Guideline on Similar Biological Medicinal Products Containing Biotechnology-Derived Proteins as Active Substance: Non-Clinical and Clinical Issues published in 2006 lays down the nonclinical and clinical requirements for a biological medicinal product claiming to be similar to another one already marketed.^[19] The nonclinical section of the guideline addresses the pharmacotoxicological assessment, and the clinical section addresses the requirements for PK, PD, and efficacy studies. Clinical safety studies as well as the risk management plan with a special emphasis on studying the immunogenicity of the biosimilar products are also required. In 2011, EMA published a concept paper on the revision of this guideline,^[20] which indicates several issues that need discussion for a potential revision. First, EMA emphasizes the need to follow the 3R principles (replacement, reduction, and refinement) with regard to the use of animal experiments. Second, a revised version of the guideline will consider a risk-based approach for the design of an appropriate nonclinical study program. Third, the guideline should be clearer considering the need and acceptance of PD markers, and what measures should be taken in case relevant markers are not available. It, however, should be noted that most recently, EMA has issued a biosimilarity guideline in October 2014, making an attempt to address these issues.^[21]

Product Class-Specific Guidelines

The principles of biosimilar drug development discussed in the former sections apply in general to all biological drug products. However, there are no standard data sets that can be applied to the approval of all classes of

biosimilars. Each class of biologic varies in its benefit/risk profile, the nature and frequency of adverse events, the breadth of clinical indications, and whether surrogate markers for efficacy are available and validated. Accordingly, the EMA has developed product class-specific guidelines that define the nature of comparative studies. So far, guidance for the development of biosimilar products has been developed for six different product classes, including erythropoietins, insulins, growth hormones, interferon alfa, granulocyte-colony stimulating factors, and low-molecular-weight heparins (LMWHs),^[22] with three more (interferon beta, follicle stimulation hormone, monoclonal antibodies).^[17,23–28]

European Experiences

As indicated earlier, the EU EMA has issued scientific guidelines on the quality, nonclinical, and clinical standards for the approval of biosimilars. EMA product class-specific guidelines (including erythropoietin, granulocyte-colony stimulating factor, insulin, growth hormone, LMWH, and interferon alfa) are available. According to these product class-specific guidelines, as of December 31, 2010, 14 biosimilar drugs have been approved in Europe. Compared to other regions in the world, Europe holds the highest number of biosimilar approvals. This number is expected to increase as many biologic patents will soon expire in the near future, which will help increase market size and competition among market participants.

Remarks

In summary, the EU has taken a thoughtful and evidence-based approach, and has established a well-documented legal and regulatory pathway for the approval of biosimilar products distinct from the generic pathway. In order to grant a biosimilar product, the EMA requires comprehensive and justified comparability studies between the biosimilar and reference products at the quality, nonclinical, and clinical level, which are explained in detail in the EMA guidelines. The approval pathway of biosimilar products in the EU is based on case-by-case reviews, owing to the complexity and diversity of the biologic products. Therefore, besides the three general guidelines, EMA also developed additional product class-specific guidelines on nonclinical and clinical studies. This approval pathway is now held up as one of the gold standards for authorizing biosimilar products.

North America

US Food and Drug Administration

For the approval of follow-on biologics in the US, current regulations depend on whether the biologic product is approved under the US Food, Drug, and Cosmetic Act (US

FD&C) or is licensed under the US Public Health Service Act (US PHS). For those biologic drugs marketed under the PHS Act, the BPCI Act passed by the US Congress on March 23, 2010, amends the PHS Act to establish an abbreviated approval pathway for biological products that are highly similar or interchangeable with an FDA-authorized biologic drug and gives the FDA the authority to approve follow-on biologics under new section 351(k) of the PHS Act. Some early biologic drugs, such as somatropin and insulin, were approved under the FD&C Act. In this case, biosimilar versions can receive approval for New Drug Applications under section 505(b)(2) of the FD&C Act.

Following the passage of the BPCI Act, in order to obtain the input on specific issues and challenges associated with the implementation of the BPCI Act from a broad group of stakeholders, the US FDA conducted a two-day public hearing on “Approval Pathway for Biosimilar and Interchangeability Biological Product” held on November 2–3, 2010, at the FDA in Silver Spring, Maryland. The scientific issues covered in this public hearing include, but are not limited to, the criteria and design for biosimilarity and interchangeability, comparability between manufacturing processes, patient safety and pharmacovigilance, exclusivity, and user fees.

In practice, there is a strong industrial interest and desire for the regulatory agencies to develop review standards and an approval process for biosimilars rather than an *ad hoc* case-by-case review of individual biosimilar applications. As indicated earlier, for this purpose, the FDA has established three committees to ensure consistency in the FDA’s regulatory approach of follow-on biologics. The three committees are the Center for Drug Evaluation and Research and Center for Biologics Evaluation and Research (CDER/CBER) Biosimilar Implementation Committee (BIC), the CDER Biosimilar Review Committee (BRC), and the CBER BRC. The CDER/CBER BRC focuses on the cross-center policy issues related to the implementation of the BPCI Act. The CDER BRC and CBER BRC are responsible for considering the requests of applicants for advice about proposed development programs for biosimilar products, reviewing biologics license applications (BLAs) that are submitted under section 351(k) of the PHS Act, and managing related issues. Thus, the review process steps of CDER BRC and CBER BRC include the following: (1) an applicant submitting request for advice, (2) internal review team meeting, (3) internal CDER BRC (CBER BRC) meeting, (4) internal post-BRC meeting, and (5) the applicant meeting with CDER (CBER).

Another important issue aroused by the BPCI Act is the interchangeability of biosimilars. Once approved, standard generic drugs can be automatically substituted for the reference product without the intervention of the health-care provider in many states. However, the automatic interchangeability cannot be applied to all biosimilars. In order to meet the higher standard of interchangeability, a sponsor must demonstrate that the biosimilar products

can be expected to produce the same clinical result as the reference product in any given patient.

On February 9, 2012, the FDA announced the publication of three draft guidance documents to assist industry in developing follow-on biologic products, including (1) Scientific Considerations in Demonstrating Biosimilarity to a Reference Product, (2) Quality Considerations in Demonstrating Biosimilarity to a Reference Protein Product, and (3) Biosimilars: Questions and Answers Regarding Implementation of the Biologics Price Competition and Innovation Act of 2009.^[1–3] Subsequently, the FDA hosted another public hearing on the discussion of these draft guidances at the FDA on May 11, 2012. Similar to the requirements of the WHO and EMA, a number of factors are considered important by the FDA when assessing applications for biosimilars, including the robustness of the manufacturing process, the demonstrated structural similarity, the extent to which mechanism of action was understood, the existence of valid, mechanistically related PD assays, comparative PK and immunogenicity, and the amount of clinical data and experience available with the original products. The guidances were later finalized in early 2015. Even though they do not provide clear standards for assessing biosimilar products, they are the first step toward removing the uncertainties surrounding the biosimilar approval pathway in the US.

Recently, following the Advisory Committee's recommendation for approval of a proposed biosimilar (by Novartis) to Amgen's Neupogen® (filgrastim) on January 7, 2015, FDA approved the proposed biosimilar on March 26, 2015. Neupogen® was originally approved by the FDA in 1991 and its patent expired in December 2013. Neupogen® was intended to decrease the incidence of infection, as manifested by febrile neutropenia in patients with nonmyeloid malignancies receiving myelosuppressive anticancer drugs associated with a clinically significant incidence of febrile neutropenia. It should be noted that the approved biosimilar of filgrastim is different from Teva's Neutroval approved by the FDA in August 2012. The approval of Teva's Neutroval was based on a full Biologics License Application (BLA) rather than under the FDA's new biosimilar approval pathway which allows Teva to compete directly with Amgen's filgrastim in the US.

Canada (Health Canada)

Health Canada, the federal regulatory authority that evaluates the safety, efficacy, and quality of drugs available in Canada, also recognizes that with the expiration of patents for biologic drugs, manufacturers may be interested in pursuing subsequent entry versions of these biologic drugs which are called subsequent entry biologics (SEB) in Canada. In 2010, Health Canada issued the "Guidance for Sponsors: Information and Submission Requirements for Subsequent Entry Biologics (SEBs)" whose objective is to provide guidance on how to satisfy the data and

regulatory requirements under the Food and Drugs Act and Regulations for the authorization of SEBs in Canada.^[29]

The concept of a SEB applies to all biologic drug products; however, there are additional criteria to determine whether the product will be eligible to be authorized as SEBs:

1. A suitable reference biologic drug exists that was originally authorized based on a complete data package and has significant safety and efficacy data accumulated.
2. The product can be well characterized by state-of-the-art analytical methods.
3. The SEB can be judged similar to the reference biologic drug by meeting an appropriate set of predetermined criteria.

With regard to the similarity of products, Health Canada requires the manufacturer to evaluate the following factors:

1. Relevant physicochemical and biological characterization data
2. Analysis of the relevant samples from the appropriate stages of the manufacturing process
3. Stability data and impurities data
4. Data obtained from multiple batches of the SEB and reference to understand the ranges in variability
5. Nonclinical and clinical data and safety studies

In addition, Health Canada also has stringent postmarketing requirements including an adverse drug reaction report, periodic safety update reports, and suspension or revocation of notice of compliance. The guidance of Canada shares similar concepts and principles as indicated in the WHO guidelines since it is clearly mentioned in the guidance that Health Canada has the intention to harmonize as much as possible with other competent regulators and international organizations.

Asia-Pacific Region (Japan, Korea, and China)

Ministry of Health, Labour and Welfare

The Japanese Ministry of Health, Labour and Welfare (MHLW) has also been confronted with the new challenge of regulating biosimilar/follow-on biologic products. Based on the similarity concept outlined by the EMA, Japan has published a guideline for the quality, safety and efficacy of biosimilar products in 2009 (MHLW 2009).^[23] The scope of the guideline includes recombinant plasma proteins, recombinant vaccines, PEGylated recombinant proteins, and nonrecombinant proteins that are highly purified and characterized. Unlike the EU, polyglycans such as LMWH have been excluded from the guideline. Another class of products excluded is synthetic peptides,

since the desired synthetic peptides can be easily defined by structural analyses and can be defined as generic drugs. Same as the requirements by the EU, the original biologic should be already approved in Japan. However, there are some differences in the requirements of stability test and toxicology studies for impurities in biosimilars between the EU and Japan. A comparison of the stability of a biosimilar with the reference innovator products as a strategy for the development of biosimilar is not always necessary in Japan. In addition, it is not required to evaluate the safety of impurities in the biosimilar product through nonclinical studies without comparing it with the original product. According to this guideline, follow-on biologics such as Somatropin and Epoetin alfa BS have been approved in Japan.

Korea Food and Drug Administration

In Korea, Pharmaceutical Affairs Act is the high-level regulation to license all medicines including biologic products. The Korean Food and Drug Administration (KFDA) notifications serve as a lower level regulation. Biologic products and biosimilars are subject to the Notification of the regulation on review and authorization of biologic products. The KFDA actively participates to promote a public dialog on the biosimilar issues. In 2008 and 2009, the KFDA held two public meetings and cosponsored a workshop to gather input on scientific and technical issues. The regulatory framework of biosimilar products in Korea is a three-tiered system: (1) Pharmaceutical Affairs Act, (2) Notification of the regulation on review and authorization of biological products, and (3) Guideline on evaluation of biosimilar products.^[30,31] As the Korean guideline for biosimilar products was developed along with that of the WHO,^[12] most of the requirements are similar except for that of the clinical evaluation to demonstrate similarity. The KFDA requires that equivalent rather than noninferior efficacy be shown in order to open the possibility of extrapolation of efficacy data to other indications of the reference product. Equivalence margins need to be pre-defined and justified, and should be established within the range which is judged not to be clinically different from reference products in clinical regards.

China Food and Drug Administration

The Center for Drug Evaluation (CDE) of the China Food and Drug Administration (CFDA) published a draft guidance for comments on October 29, 2014.^[32] The CFDA finalized the draft guidance and published a current trial version on February 28, 2015.^[33] In this version, one significant change is to relax the regulation for the selection of reference product for comparison. In the version for comments, the CFDA requires the reference product to be the originator product authorized by the CFDA. In the current trial version, the CFDA has removed this restriction. In

other words, EU-approved and/or US-licensed reference products can be used as the reference products. In addition, for PK studies, the traditional 80%–125% equivalence range is not mandatory. In the current trial version, the CFDA indicates that an alternative equivalence range (e.g., SABE for highly variable drugs [HVDs]) can be used if scientifically justifiable.

CRITERIA FOR BIOSIMILARITY

As indicated in Chow and Liu,^[34] bioequivalence assessment for generic drug products is possible under the Fundamental Bioequivalence Assumption. It states that if two drug products are shown to be bioequivalent in the drug absorption profile (which is measured in terms of the extent and rate of absorption), it is assumed that they will reach the same therapeutic effect or they are therapeutically equivalent. The Fundamental Bioequivalence Assumption assumes that there is association between PK responses and clinical outcomes. This assumption, however, may not be applicable for the assessment of biosimilarity of biosimilars due to the fundamental differences between generic (small-molecule) drug products and similar biological (large-molecule) drug products (see Table 2). In what follows, several criteria for the primary assessment of bioequivalence or similarity, which have been proposed by the FDA, are discussed for their applicability to the assessment of biosimilarity.

Average Bioequivalence (Biosimilarity)

For the assessment of average bioequivalence (ABE) both *in vivo* and *in vitro*, FDA adopted a one-size-fits-all criterion. That is, for *in vivo* (*in vitro*) bioequivalence

Table 2 Fundamental differences between generic drugs and biosimilars

Generic drugs	Biologic drugs (biosimilars)
Made by chemical synthesis	Made by living cells
Defined structure	Heterogeneous structure
	Mixtures of related molecules
Easy to characterize	Difficult to characterize
Relatively stable	Variable
	Sensitive to environmental conditions such as light and temperature
No issue of immunogenicity	Issue of immunogenicity
Usually taken orally	Usually injected
Often prescribed by a general practitioner	Usually prescribed by specialists

assessment, a test drug product is said to be bioequivalent to a reference drug product if the estimated 90% confidence interval for the geometric mean ratio (GMR) of the primary PK parameters, e.g., area under the blood or plasma concentration–time curve (AUC) and maximum concentration (C_{max}), is totally within the bioequivalence limits of 80.00%–125.00% (90.00%–111.11%). See, e.g., Chow and Liu^[34]; FDA.^[35]

The one-size-fits-all criterion does not take into consideration the therapeutic window (TW) and intra-subject variability of a drug which have been identified to have non-negligible impact on the safety and efficacy of generic drug products compared to the innovative drug products. In the past several decades, this one-size-fits-all criterion has been challenged and criticized by many researchers. It was suggested that flexible criteria in terms of safety (upper bioequivalence limit) and efficacy (lower bioequivalence limit) should be developed based on the characteristics of the drug, its TW, and intra-subject variability (ISV) (see Table 3).

On the other hand, for orally administered drugs with high within-subject variability and wide TW (Class D, HVDs, see Table 3), the regulatory expectation has become, in some cases, more relaxed. For these drugs, the approach of scaled average bioequivalence (SABE) has been proposed. This method is, in fact, a special case of the procedure described earlier for individual BE when the within-subject variation is high ($\sigma_{WR}^2 > \sigma_{W0}^2$). However, the current FDA guidance does not contain special provisions for this class of drugs.

The assessment of ABE focuses on average bioavailability but ignores the variability associated with the PK responses. Thus, two drug products may fail the evaluation of ABE if the variability associated with the PK responses is large even though they have identical means. A drug with large variability is considered highly variable. The FDA defines an HVD as a drug whose within-subject (or intra-subject) variation is larger than or equal to 30%. This definition is based on intra-subject variation, however, rather arbitrary. One of the problematic aspects of this definition is that the estimated within-subject variability depends on the metrics of PK responses such as AUC and C_{max} . Haidar et al.^[36] pointed out that HVDs show variable PK as a result of their inherent properties (e.g., distribution,

systemic metabolism, and elimination) (see also, Haidar et al., Tothfalusi et al., Davit et al.).^[37–39] A drug may have low variability if it is administered intravenously, whereas it can be highly variable after oral administration.

In practice, HVDs often fail to meet the current regulatory acceptance criteria for ABE. In the last decade, the topic for evaluation of bioequivalence for HVDs has received much attention. This topic has been discussed several times at regulatory forums and international conferences, but academics, representatives of pharmaceutical industries, and regulatory agencies failed to reach a consensus until recently, and an approach of SABE was proposed by Haidar et al.^[36,39] The approach of SABE is briefly described below.

Logarithmic means the two drug products, denoted by μ_T and μ_R , respectively, are typically compared. The acceptance of bioequivalence is claimed if the difference between the logarithmic means is between prespecified regulatory limits. The limits (θ_A) are generally symmetrical on the logarithmic scale and usually equal $\pm \ln(1.25)$. Thus, the criterion for ABE can be expressed as follows:

$$-\theta_A \leq \mu_T - \mu_R \leq \theta_A$$

In a bioequivalence study, the individual kinetic responses are evaluated from the measured concentrations. The means of the logarithmic responses of the two formulations are calculated. These sample averages estimate the true population means. A variance is also estimated for each kinetic response. It is a measure of the intra-subject variance but not always identical to it. The FDA suggests that the above ABE could be scaled by a standard deviation as follows:

$$-\theta_s \leq \frac{(\mu_T - \mu_R)}{\sigma_w} \leq \theta_s,$$

where θ_s is the SABE regulatory cutoff. Here the standard deviation (σ_w) is the within-subject standard deviation. In a replicate design, σ_w is generally the within-subject standard deviation of the reference formulation (denoted by σ_{WR}). Thus, the scaling factor of SABE has similar features to the scaling factor of IBE.

Population/Individual Bioequivalence

In the early 1990s, as more generic drug products became available, it was a concern whether the use of generic drug products was safe and whether the approved generic drug products could be used interchangeably. The FDA indicates that an approved generic drug product can be used to substitute the innovative (brand-name) drug product. However, the FDA does not indicate that generic drug products can be used interchangeably. Since generic drug products are approved based on the criterion of the 80/125 rule, there may be a drastic change in blood concentration

Table 3 Classification of drugs

Class	TW	ISV	Example
A	Narrow	High	Cyclosporine
B	Narrow	Low	Theophylline
C	Wide	Low to moderate	Most drugs
D	Wide	High	Chlorpromazine or topical corticosteroids

TW, therapeutic window; ISV, intra-subject variability.

if one shall switch from one generic drug to another. For example, if one switched from a drug that was approved on the lower end of the 80/125 rule (say 80%) to another drug that was approved on the higher end of the 80/125 rule (say 120%), then there would be a sudden 50% increase in blood concentration, which may cause a potential safety concern. In order to address the issue of drug interchangeability in terms of drug prescribability and switchability, between the early 1990s and the early 2000s, the FDA suggested using the concepts of population bioequivalence for addressing drug prescribability and individual bioequivalence for addressing drug switchability.

Let y_T be the PK response from the test product, and y_R and $y_{R'}$ be two identically distributed PK responses from the reference product. Now consider a measure of the relative difference between the mean squared errors of $y_T - y_R$ and $y_R - y_{R'}$. Thus,

$$\theta = \begin{cases} \frac{E(y_T - y_R)^2 - E(y_R - y_{R'})^2}{E(y_R - y_{R'})^2 / 2} & \text{if } E(y_R - y_{R'})^2 / 2 \geq \sigma_0^2 \\ \frac{E(y_T - y_R)^2 - E(y_R - y_{R'})^2}{\sigma_0^2} & \text{if } E(y_R - y_{R'})^2 / 2 < \sigma_0^2 \end{cases}$$

where σ_0^2 is a given constant. If y_T , y_R , and $y_{R'}$ are independent observations from different subjects, then the two drug products show population bioequivalence when $\theta < \theta_p$. On the other hand, if y_T , y_R and $y_{R'}$ are independent observations from the same subject, then the two drug products exhibit individual bioequivalence when $\theta < \theta_i$. Thus, as indicated in section “North America,” for the assessment of individual bioequivalence, the criterion proposed in the FDA guidance^[40] can be expressed as

$$\theta_i = (\delta^2 + \sigma_D^2 + \sigma_{WT}^2 - \sigma_{WR}^2) / \max\{\sigma_{W0}^2, \sigma_{WR}^2\}, \quad (1)$$

where $\delta = \mu_T - \mu_R$, σ_{WT}^2 , σ_{WR}^2 , σ_D^2 are the true difference in means, intra-subject variabilities of the test product and the reference product, and variance component due to subject-by-formulation interaction between drug products, respectively. σ_{W0}^2 is the scale parameter specified by the user or regulator. Similarly, the criterion for the assessment of population bioequivalence suggested in the FDA guidance^[40] is given by

$$\theta_p = (\delta^2 + \sigma_{TT}^2 - \sigma_{TR}^2) / \max\{\sigma_{T0}^2, \sigma_{TR}^2\}, \quad (2)$$

where σ_{TT}^2 , σ_{TR}^2 are the total variances for the test product and the reference product, respectively, and σ_{T0}^2 is the scale parameter specified by the user or regulator.

A typical approach is to construct a one-sided 95% confidence interval for θ_i (θ_p) for the assessment of individual (population) bioequivalence. If the one-sided 95% upper confidence limit is less than the bioequivalence limit of

θ_i (θ_p), we then conclude that the test product is bioequivalent to that of the reference product in terms of individual (population) bioequivalence.

Masking Effect

The goal for evaluation of bioequivalence is to assess the similarity of the distributions of the PK metrics obtained either from the population or from individuals in the population. Under aggregate criteria, however, different combinations of values for the components of the aggregate criterion can yield the same value. In other words, bioequivalence can be reached by two totally different distributions of PK metrics. This is another artifact of the aggregate criteria. At the 1996 advisory committee meeting, it was reported that a 14% increase in the average (ABE only allows 80%–125%) is offset by a 48% difference in the variability, and the test passes IBE but fails ABE. More details regarding individual and population bioequivalence can be found in the works of Chow and Liu^[34] and Chow.^[41]

Profile Analysis for *In Vitro* Bioequivalence Testing

As indicated in the FDA draft guidance for *in vitro* bioequivalence testing, profile analysis using a confidence interval approach should be applied to cascade impactor or multistage liquid impinger for particle size distribution. Equivalence may be assessed based on chi-square differences. The idea is to compare the profile difference between the test product and reference product samples with the profile variation between reference product samples. More specifically, let y_{ijk} denote the observation from the j th subject's i th stage of the k th treatment. Given a sample (j_0) from the test product and two samples (j_0 , j_1) from the reference products and assuming that there are a total of S stages, the profile distance between the test and reference samples is given by

$$d_{TR} = \sum_{i=1}^S \frac{(y_{i0T} - 0.5(y_{i1R} + y_{i2R}))^2}{(y_{i0T} + 0.5(y_{i1R} + y_{i2R}))}.$$

Similarly, the profile variability within reference is defined as

$$d_{RR} = \sum_{i=1}^S \frac{(y_{i1R} - y_{i2R})^2}{0.5(y_{i1R} + y_{i2R})}.$$

For a given triplet sample of (Test, Reference 1, Reference 2), the ratio of d_{TR} and d_{RR} , i.e.,

$$rd = \frac{d_{TR}}{d_{RR}} \quad (3)$$

can then be used as a bioequivalence measure for the triplet samples between the two drug products. For a

selected sample, the 95% upper confidence bound of $E(rd) = E(d_{TR}/d_{RR})$ is then used as a bioequivalence measure for the determination of bioequivalence. In other words, if the 95% upper confidence bound is less than the bioequivalence limit, then we claim that the two products are bioequivalent. The FDA draft guidance recommends a bootstrap procedure to construct the 95% upper bound for $E(rd)$. The procedure is described below.

Assume that the samples are obtained in a two-stage sampling manner. In other words, for each treatment (test or reference), three lots are randomly sampled. Within each lot, ten samples (e.g., bottles or canisters) are sampled. The following is quoted from the 1999 FDA draft guidance regarding the bootstrap procedure to establish profile bioequivalence. For an experiment consisting of three lots each of test and reference products, and with ten canisters per lot, the lots can be matched into six different combinations of triplets with two different reference lots in each triplet. The ten canisters of a test lot can be paired with the ten canisters of each of the two reference lots in $(10 \text{ factorial})^2 = (3,628,800)^2$ combinations in each of the lot triplets. Hence, a random sample of the N -canister pairing of the six Test-Reference 1-Reference 2 lot triplets is needed. rd is estimated by the sample mean of the rd 's calculated for the triplets in ten selected samples of N . Note that the FDA recommends that $N = 500$ be considered.

Similarity Factor for Dissolution Profile Comparison

In vivo bioequivalence studies are surrogate trials for assessing equivalence between test and reference formulations based on the rate and extent of drug absorption in humans to establish similar effectiveness and safety under the Fundamental Bioequivalence Assumption. However, drug absorption depends on the dissolved state of drug product, and dissolution testing provides a rapid *in vitro* assessment of the rate and extent of drug release. Leeson,^[42] therefore, suggested that *in vitro* dissolution testing be used as a surrogate for *in vivo* bioequivalence studies to assess equivalence between the test and reference formulations for postapproval changes. For the comparison of dissolution profiles, the US FDA guidance suggests considering the assessment of (1) the overall profile similarity and (2) similarity at each sampling time point.^[43] Since dissolution profiles are curves over time, Chow and Ki^[44] introduced the concepts of local similarity and global similarity. Two dissolution profiles are said to be locally similar at a given time point if their difference or ratio at the given time point is within some equivalence (similarity) limits, denoted by (δ_L, δ_U) . Two dissolution profiles are considered globally similar if their differences or ratios are within (δ_L, δ_U) across all time points. Note that global similarity is also known as *uniformly similar*. Chow and Ki^[44] suggested

the following similarity limits for comparing dissolution profiles:

$$\delta_L = \frac{Q - \delta}{Q + \delta} \text{ and } \delta_U = \frac{Q + \delta}{Q - \delta},$$

where Q is the desired mean dissolution rate of a drug product as specified in the United States Pharmacopeia and National Formulary individual monograph, and δ is a meaningful difference of scientific importance in mean dissolution profiles of two drug products under consideration. In practice, δ is usually determined by a pharmaceutical scientist.

In order to achieve these two objectives, based on Moore and Flanner,^[45] both the FDA Scale-Up and Post-Approval Change (SUPAC) guidance^[46] and the guidance on dissolution testing^[43] suggest the similarity and difference factors for the assessment of similarity. The similarity factor is then defined as the logarithmic reciprocal square root transformation of 1 plus the mean-squared (the average sum of squares) difference in mean cumulative percentage dissolved between the test and reference formulations over all sampling time points. That is,

$$f_2 = 50 \log \left\{ \left[1 + \frac{Q}{n} \right]^{-0.5} 100 \right\} \quad (4)$$

where

$$Q = \sum_{t=1}^n (\mu_{Rt} - \mu_{Tt})^2,$$

and $\log$ denotes the logarithm base 10.

On the other hand, the difference factor is the sum of the absolute difference in mean cumulative percentage dissolved between the test and reference formulations divided by the sum of the mean cumulative dissolved of the reference formulation.

$$f_1 = \frac{\sum_{t=1}^n |\mu_{Rt} - \mu_{Tt}|}{\sum_{t=1}^n \mu_{Rt}} \quad (5)$$

It should be noted that the definitions of f_1 and f_2 provided by Moore and Flanner,^[45] and in the SUPAC and guidance on dissolution testing are not clear whether they are defined based on the population means or the sample averages. However, following the traditional statistical inference with the ability for evaluation of error probability, we define both f_1 and f_2 based on the population mean dissolution rates. It follows that f_1 and f_2 are the population parameters for the assessment of similarity of dissolution profiles between the test and reference formulations.

The use of the f_2 similarity factor has been discussed and criticized by many researchers.^[47–49] Chow and Shao^[50] pointed out two main problems in using the f_2 similarity factor for assessing similarity between the dissolution profiles of two drug products. The first problem is its lack of statistical justification. Since f_2 is a statistic and, thus, a random variable, $P(f_2 > 50)$ may be quite large when the two dissolution profiles are not similar. However, $P(f_2 > 50)$ can be very small when the two dissolution profiles are similar. Suppose the expected value $E(f_2)$ exists and that we can find a 95% lower confidence bound for $E(f_2)$. Then, a reasonable modification to the f_2 similarity factor approach is to replace f_2 with the 95% lower confidence bound for $E(f_2)$. The second problem with using the f_2 similarity factor is that the f_2 similarity factor assesses neither local similarity nor global similarity, owing to the use of the average of the dissolution data.

STATISTICAL METHODS

For the assessment of biosimilarity of biosimilar products, standard methods for the assessment of bioequivalence for small-molecule drug products are usually considered. These methods include the classical methods such as the confidence interval approach and interval hypothesis testing such as Schuirmann's two one-sided tests procedure, Bayesian methods, and nonparametric methods such as Wilcoxon–Mann–Whitney two one-sided tests procedure. It should be noted that these methods were derived based on a raw data model under a crossover design although they can be easily extended to a parallel group design based on log-transformed data. In practice, it is a concern whether these methods are appropriate for the assessment of biosimilarity of biosimilar products due to fundamental differences between small-molecule drug products and large-molecule biological drug products as described in earlier articles.^[51] As a result, the search for biosimilarity criteria, study endpoints (measures of biosimilarity), and statistical methods has become the center of attention for the assessment of biosimilarity of biosimilar products within regulatory agencies.

Interval Hypotheses

In practice, one of the most widely used designs for assessing biosimilarity between biosimilar products and an innovator biological product is probably either a two-sequence, two-period (2×2) crossover design or a two-arm parallel group design. Under a valid study design, biosimilarity can then be assessed by means of an equivalence test under the following interval hypotheses:

$$H_0: \mu_T - \mu_R \leq \theta_L \text{ or } \mu_T - \mu_R \geq \theta_U \text{ vs. } H_a: \theta_L < \mu_T - \mu_R < \theta_U, \quad (6)$$

where (θ_L, θ_U) are the prespecified equivalence limits (margins), and μ_T and μ_R are the population means of a biological (test) product and an innovator biological (reference) product, respectively. That is, biosimilarity is assessed in terms of the *absolute* difference between the two population means. Alternatively, biosimilarity can be assessed in terms of the *relative* difference (i.e., ratio) between the population means. Note that for the assessment of similarity between small-molecule drug products, average bioequivalence, population bioequivalence, and individual bioequivalence are defined in terms of ratios of appropriate parameters under a crossover design. In practice, since many biological products have long half-lives, a crossover design may not be appropriate in these cases for the assessment of biosimilarity. Instead, a parallel group design is considered more appropriate.

The purpose of this article is to provide a comprehensive summarization of standard statistical methods that are commonly used for the assessment of average bioequivalence for small-molecule drug products under a crossover design. In addition, we will focus on the discussion of statistical methods proposed by Kang and Chow^[52] under a newly proposed three-arm parallel design for investigation of biosimilarity of biosimilar products. The statistical analysis methods proposed by Kang and Chow^[52] consider the relative distance based on the absolute mean differences. Under the three-arm design, patients who are randomly assigned to the first group receive a biosimilar (test) product, while patients who are randomly assigned to the second and third groups receive the innovator biological (reference) product from different batches. The distance between the test product and the reference product is defined by the absolute mean difference between two products. Similarly, the distance between the reference products from two different batches is defined. The relative distance is defined as the ratio of the two distances whose denominator is the distance between the two reference products from different batches. Under the proposed design, Kang and Chow^[52] claim that the two products are biosimilar if the relative distance is less than a prespecified margin.

Classic Methods for Assessing Biosimilarity

Under a crossover design, consider the following statistical model for raw data:

$$Y_{ijk} = \mu + S_{ik} + P_j + F_{j,k} + C_{(j-1,k)} + e_{ijk}, \quad (7)$$

where Y_{ijk} is the response (e.g., AUC) of the i th subject in the k th sequence at the j th period; μ is the overall mean; S_{ik} is the random effect of the i th subject in the k th sequence, where $i = 1, 2, \dots, g$; P_j is the fixed effect of the j th period, where $j = 1, \dots, p$ and $\sum_j P_j = 0$; $F_{(j,k)}$ is the direct fixed effect of the drug product in the k th sequence which is

administered at the j th period, and $\Sigma F_{(j,k)} = 0$; $C_{(j-1,k)}$ is the fixed first-order carryover effect of the drug product in the k th sequence which is administered at the $(j-1)$ th period, where $C_{(0,k)} = 0$ and $\Sigma C_{(j-1,k)} = 0$; and e_{ijk} is the (within-subject) random error in observing Y_{ijk} .

It is assumed that $\{S_{ik}\}$ are independently and identically distributed (i.i.d.) with mean 0, and variance σ_s^2 and $\{e_{ijk}\}$ are independently distributed with mean 0 and variances σ_t^2 where $t = 1, 2, \dots, L$ (the number of formulations to be compared). $\{S_{ik}\}$ and $\{e_{ijk}\}$ are assumed mutually independent. The estimate of σ_s^2 is usually used to explain the intersubject variability, and the estimates of σ_t^2 are used to assess the intra-subject variabilities for the t th drug product.

Confidence Interval Approach

For bioequivalence assessment of small-molecule drug products, the FDA adopts the 80/125 rule based on log-transformed data. The 80/125 rule states that bioequivalence is concluded if the GMR between the test product and the reference product is within the bioequivalence limits of (80.00%, 125.00%), with a certain statistical assurance. Thus, a typical approach is to consider the method of classic (shortest) confidence interval.

Consider a standard two-sequence, two-period cross-over design, under model (7), after the log transformation of the data, let $\bar{Y}_T$ and $\bar{Y}_R$ be the respective least squares means for the test and reference formulations that can be obtained from the sequence-by-period means. The classic (or shortest) $(1 - 2\alpha) \times 100\%$ confidence interval can then be obtained based on the following t statistic:

$$T = \frac{(\bar{Y}_T - \bar{Y}_R) - (\mu_T - \mu_R)}{\hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}, \quad (8)$$

where n_1 and n_2 are the numbers of subjects in sequences 1 and 2, respectively, and $\hat{\sigma}_d$ is an estimate of the variance of the period differences for each subject within each sequence, which are defined as follows:

$$d_{ik} = \frac{1}{2}(Y_{i2k} - Y_{i1k}), \quad i = 1, 2, \dots, n_k; \quad k = 1, 2.$$

Thus, $V(d_{ik}) = \sigma_d^2 = \sigma_e^2/2$. Under normality assumptions, T follows a central student t distribution with degrees of freedom $n_1 + n_2 - 2$. Thus, the classic $(1 - 2\alpha) \times 100\%$ confidence interval for $\mu_T - \mu_R$ can be obtained as follows:

$$\begin{aligned} L_1 &= (\bar{Y}_T - \bar{Y}_R) - t(\alpha, n_1 + n_2 - 2) \hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}, \\ U_1 &= (\bar{Y}_T - \bar{Y}_R) + t(\alpha, n_1 + n_2 - 2) \hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}. \end{aligned} \quad (9)$$

The above $(1 - 2\alpha) \times 100\%$ confidence interval for $\log(\mu_T) - \log(\mu_R) = \log(\mu_T/\mu_R)$ can be converted into a $(1 - 2\alpha) \times 100\%$ confidence interval for μ_T/μ_R by taking an anti-log transformation.

Note that under a parallel group design, a $(1 - 2\alpha) \times 100\%$ confidence interval for μ_T/μ_R can be similarly obtained.

Schirmann's Two One-Sided Tests Procedure

The assessment of average bioequivalence is based on the comparison of bioavailability profiles between the two products. However, in practice, it is recognized that no two drug products will have exactly the same bioavailability profiles. Therefore, if the profiles of the two drug products differ by less than a (clinically) meaningful limit, the profiles of the two drug products may be considered equivalent. Following this concept, Schirmann^[53] first introduced the use of interval hypotheses (6) for assessing average bioequivalence. The concept of interval hypotheses (6) is to show average bioequivalence by rejecting the null hypothesis of average bioinequivalence. In most bioavailability and bioequivalence studies, δ_L and δ_U are often chosen to be $-\theta_L = \theta_U = 20\%$ of the reference mean (μ_R). When the natural logarithmic transformation of the data is considered, the hypotheses corresponding to hypotheses (6) can be stated as

$$H'_0: \mu_T/\mu_R \leq \delta_L \quad \text{or} \quad \mu_T/\mu_R \geq \delta_U \quad \text{vs.} \quad H'_a: \delta_L < \mu_T/\mu_R < \delta_U \quad (10)$$

where $\delta_L = \exp(\theta_L)$ and $\delta_U = \exp(\theta_U)$. Note that the FDA recommends that $(\delta_L, \delta_U) = (80.00\%, 125.00\%)$ for assessing average bioequivalence.

Note that the test for hypotheses in Eq. (10) formulated on the log scale is equivalent to testing for hypotheses (6) on the raw scale. The interval hypotheses (6) can be decomposed into two sets of one-sided hypotheses:

$$\begin{aligned} H_{01}: \mu_T - \mu_R \leq \theta_L \quad \text{vs.} \quad H_{a1}: \mu_T - \mu_R > \theta_L \\ \text{and} \\ H_{02}: \mu_T - \mu_R \geq \theta_U \quad \text{vs.} \quad H_{a2}: \mu_T - \mu_R < \theta_U \end{aligned} \quad (11)$$

The first set of hypotheses is to verify that the average bioavailability of the test formulation is not too low, whereas the second set of hypotheses is to verify that the average bioavailability of the test formulation is not too high. A relatively low (or high) average bioavailability may refer to the concern of efficacy (or safety) of the test formulation. If one concludes that $\theta_L < \mu_T - \mu_R$ (i.e., reject H_{01}) and $\mu_T - \mu_R < \theta_U$ (i.e., reject H_{02}), then it has been concluded that

$$\theta_L < \mu_T - \mu_R < \theta_U.$$

Thus, μ_T and μ_R are equivalent. The rejection of H_{01} and H_{02} , which leads to the conclusion of average bioequivalence, is equivalent to the rejection of H_0 in Eq. (6).

Under hypotheses (6), Schuirmann^[54] introduced the two one-sided tests procedure for assessing the average bioequivalence between drug products. The proposed two one-sided tests procedure suggests the conclusion of equivalence of μ_T and μ_R at the α level of significance if, and only if, H_{01} and H_{02} in Eq. (11) are rejected at a predetermined α -level of significance. Under normality assumptions, the two sets of one-sided hypotheses can be tested with ordinary one-sided t -tests. We conclude that μ_T and μ_R are average equivalent if

$$T_L = \frac{(\bar{Y}_T - \bar{Y}_R) - \theta_L}{\hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} > t(\alpha, n_1 + n_2 - 2)$$

and

$$T_U = \frac{(\bar{Y}_T - \bar{Y}_R) - \theta_U}{\hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} < -t(\alpha, n_1 + n_2 - 2). \quad (12)$$

The two one-sided t -tests procedure is operationally equivalent to the classic (shortest) confidence interval approach; that is, both the classic confidence interval approach and Schuirmann's two one-sided tests procedure will lead to the same conclusion on bioequivalence.

Note that under a parallel group design, Schuirmann's two one-sided tests procedure can be similarly derived with a slightly modification from a paired t -test statistic to a two-sample t -test statistic.

Bayesian Methods

In previous sections, statistical methods for the assessment of biosimilarity were derived based on the sampling distribution of the estimate of the parameter of interest, such as the direct drug effect (i.e., $\theta = \mu_T - \mu_R$), which is assumed to be fixed but unknown. Although statistical inference (e.g., confidence interval and interval hypothesis testing) on the unknown direct drug effect can be drawn from the sampling distribution of the estimate, there is little information on the probability of the unknown direct drug effect being within the equivalence limits (θ_L, θ_U). To have a certain assurance on the probability of the direct drug effect being within (θ_L, θ_U), a Bayesian approach,^[55] which assumes that the unknown direct drug effect is a random variable and follows a prior distribution, is useful.

In practice, before a biosimilar study is conducted, investigators may have some prior knowledge of the drug product under development. As an example, for a PK biosimilar study, according to past experiments, the investigator may have some information on (1) the intersubject and the intra-subject variabilities and (2) the ranges of AUC or C_{max} for the test and reference products. This information can be used to choose an appropriate prior distribution

of the unknown direct drug effect. An appropriate prior distribution can reflect the investigator's belief about the drug products under study. After the study is completed, the observed data can be used to adjust the prior distribution of the direct drug effect, which is called the posterior distribution. Given the posterior distribution, a probability statement on the direct drug effect being within the biosimilarity limits can be made.

A different prior distribution can lead to a different posterior distribution that has an influence on the statistical inference on the direct drug effect. Thus, an important issue in a Bayesian approach is how to choose a prior distribution. Box and Tiao^[55] introduced the use of a locally uniform distribution over a possible range of AUC or C_{max} as a non-informative prior distribution. A non-informative prior distribution assumes that there is an equally likely chance for any two points within the possible range being the true state of the location of the direct drug effect. In this case, the resultant posterior distribution can be used to provide the true state of the location of a direct drug effect. In practice, however, it is also desirable to provide an interval showing a range in which most of the distribution of a direct drug effect will fall. We shall refer to such an interval as a highest posterior density (HPD) interval. The HPD interval is also known as a credible interval^[56] or a Bayesian confidence interval.^[57] An HPD interval possesses the following properties^[55]: (1) the density for every point inside the interval is greater than that for every point outside the interval, and (2) for a given probability distribution, the interval is the shortest. It can be verified that the above two properties imply each other.

In what follows, for illustration purposes, the Bayesian method proposed by Rodda and Davis^[58] is discussed under the following model, which assumes that there are no carryover effects because a washout period of sufficient length can be chosen to completely eliminate the residual effects from one dosing period to the next:

$$Y_{ijk} = \mu + S_{ik} + F_{(j,k)} + P_j + e_{ijk}, \quad (13)$$

where Y_{ijk} , μ , S_{ik} , $F_{(j,k)}$, P_j , and e_{ijk} were defined in Eq. (7). Given the results of a biosimilar study, Rodda and Davis^[58] proposed a Bayesian evaluation to estimate the probability of a clinically important difference (i.e., the probability that the true direct drug effect will fall within the bioequivalent limits is estimated). Under the assumption of normality and equal carryover effects, $\bar{d}_1$, $\bar{d}_2$ and $(n_1 + n_2 - 2)\hat{\sigma}_d^2$ are independently distributed as $N(\theta_1, \sigma_d^2/n_1)$, $N(\theta_2, \sigma_d^2/n_2)$, and $\sigma_d^2 \chi^2(n_1 + n_2 - 2)$, where

$$\bar{d}_{.k} = \frac{1}{n_k} \sum_{i=1}^{n_k} d_{ik}, \quad k = 1, 2$$

$$\theta_1 = \frac{1}{2}[(P_2 - P_1) + (F_T - F_R)],$$

$$\theta_2 = \frac{1}{2}[(P_2 - P_1) + (F_R - F_T)].$$

$$\begin{aligned}\text{Note that } F &= \theta_1 - \theta_2 = (\mu + F_T) - (\mu + F_R) \\ &= \mu_T - \mu_R\end{aligned}$$

Assuming that the non-informative prior distribution for θ_1 , θ_2 , and $\log(\sigma_d)$ is approximately independent and locally uniformly distributed, then the joint posterior distribution of θ_1 , θ_2 , and σ_d^2 , given data $Y = \{Y_{ijk}, i = 1, 2, \dots, n_k; j, k = 1, 2\}$, is

$$p(\theta_1, \theta_2, \sigma_d^2 | \mathbf{Y}) = p(\theta_1 | \sigma_d^2, \bar{d}_1) p(\theta_2 | \sigma_d^2, \bar{d}_2) p(\sigma_d^2 | \hat{\sigma}_d^2), \quad (14)$$

$$\begin{aligned}p(\theta_i | \sigma_d^2, \bar{d}_i) &= N(\bar{d}_i, \hat{\sigma}_d^2/n_i), \quad i = 1, 2, \\ p(\sigma_d^2 | \hat{\sigma}_d^2) &= (n_1 + n_2) \hat{\sigma}_d^2 \chi^2(n_1 + n_2 - 2).\end{aligned}$$

where $\chi^2(n_1 + n_2 - 2)$ is the distribution of the inverse of $\chi^2(n_1 + n_2 - 2)$. Therefore, the joint distribution of $\mu_T - \mu_R (=F)$ and σ_d^2 is given by

$$p(\mu_T - \mu_R, \sigma_d^2 | \mathbf{Y}) = p(\mu_T - \mu_R | \sigma_d^2, \bar{d}_1 - \bar{d}_2) p(\sigma_d^2 | \hat{\sigma}_d^2), \quad (15)$$

where

$$\begin{aligned}p(\mu_T - \mu_R | \sigma_d^2, \bar{d}_1 - \bar{d}_2) &= N\left[\bar{d}_1 - \bar{d}_2, \hat{\sigma}_d^2 \left(\frac{1}{n_1} + \frac{1}{n_2}\right)\right] \\ &= N\left[\bar{Y}_T - \bar{Y}_R, \hat{\sigma}_d^2 \left(\frac{1}{n_1} + \frac{1}{n_2}\right)\right].\end{aligned}$$

The marginal posterior distribution of F , given data $\mathbf{Y}$, is

$$\begin{aligned}p(\mu_T - \mu_R | \mathbf{Y}) &= \frac{(\hat{\sigma}_d^2 m)^{-1/2}}{B(1/2, v/2) \sqrt{n}} \\ &\quad \left\{ 1 + \frac{[(\mu_T - \mu_R) - (\bar{Y}_T - \bar{Y}_R)]^2}{v \hat{\sigma}_d^2 m} \right\}^{-(v+1)/2}, \quad (16)\end{aligned}$$

where $m = \frac{1}{n_1} + \frac{1}{n_2}$, $v = n_1 + n_2 - 2$, and $-\infty < \mu_T - \mu_R < \infty$.

Thus, we have

$$T_{RD} = \frac{(\mu_T - \mu_R) - (\bar{Y}_T - \bar{Y}_R)}{\hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \quad (17)$$

which has a central Student's t -distribution with $n_1 + n_2 - 2$ degrees of freedom. From Eq. (17), the probability of F being within the biosimilarity limits of (θ_L, θ_U) can be estimated by

$$\begin{aligned}P_{RD} &= P\{\theta_L < \mu_T - \mu_R < \theta_U\} \\ &= F_t(t_U) - F_t(t_L),\end{aligned} \quad (18)$$

where F_t is the cumulative distribution function of a central t variable with $n_1 + n_2 - 2$ degrees of freedom, and

$$\begin{aligned}t_U &= \frac{\theta_U - (\bar{Y}_T - \bar{Y}_R)}{\hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \\ \text{and} \\ t_L &= \frac{\theta_L - (\bar{Y}_T - \bar{Y}_R)}{\hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}.\end{aligned} \quad (19)$$

The lower and upper limits of the $(1 - 2\alpha) \times 100\%$ HPD interval are, respectively, given by

$$\begin{aligned}L_{RD} &= (\bar{Y}_T - \bar{Y}_R) - t(\alpha, n_1 + n_2 - 2) \hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}, \\ U_{RD} &= (\bar{Y}_T - \bar{Y}_R) + t(\alpha, n_1 + n_2 - 2) \hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}.\end{aligned} \quad (20)$$

Hence, it is verified that the $(1 - 2\alpha) \times 100\%$ HPD interval in Eq. (20) is numerically equivalent to the $(1 - 2\alpha) \times 100\%$ classic confidence interval obtained from the sampling theory. However, the interpretation of these two intervals is totally different. For example, a 90% classic confidence interval for F indicates that, in the long run, if the study is repeatedly carried out for numerous times, 90% of the times the interval will contain the unknown direct drug effect $\mu_T - \mu_R$. On the other hand, based on the posterior distribution of $\mu_T - \mu_R$, the chance of $\mu_T - \mu_R$ being within the lower and upper limits of a 90% HPD interval is 90%.

Wilcoxon–Mann–Whitney Two One-Sided Tests Procedure

As described in the previous sections, statistical methods for assessing average biosimilarity between drug products were derived under the assumption that $\{S_{ik}\}$ and $\{e_{ijk}\}$ are mutually independent and normally distributed with mean 0 and variance σ_s^2 and σ_e^2 . Under these normality assumptions, confidence intervals and tests for interval hypotheses were obtained based on either a two-sample t -statistic or an F -statistic. In practice, however, one of the difficulties commonly encountered in comparing drug products is whether the assumption of normality (for raw or untransformed data) or log-normality (for log-transformed data) is valid. If the normality (or log-normality) is seriously violated, the approach based on a two-sample t -statistic or an F -statistic is no longer justified. In this situation, a distribution-free (or nonparametric) method is useful. In this section, a nonparametric version of the two one-sided tests procedure for testing interval hypotheses, namely, Wilcoxon–Mann–Whitney two one-sided tests procedure, is discussed. The Hodges–Lehmann estimator associated with the Wilcoxon rank sum test will be

used to construct a $(1 - 2\alpha) \times 100\%$ confidence interval for $\mu_T - \mu_R$, the difference in average biosimilarity.

Under the standard 2×2 crossover design consisting of a pair of dual sequences (i.e., RT and TR), a distribution-free rank sum test can be applied directly to the two one-sided tests procedure.^[59,60] We shall refer to this approach as Wilcoxon–Mann–Whitney two one-sided tests procedure. Let $\theta = \mu_T - \mu_R$. The two sets of hypotheses in Eq. (6) can then be rewritten as

$$H_{01} : \theta_L^* \leq 0 \quad \text{vs.} \quad H_{a1} : \theta_L^* > 0$$

and

$$H_{02} : \theta_U^* \geq 0 \quad \text{vs.} \quad H_{a2} : \theta_U^* < 0,$$

where $\theta_L^* = \theta - \theta_L$ and $\theta_U^* = \theta - \theta_U$.

Thus, the estimates of θ_L^* and θ_U^* can be obtained as a linear function of period differences d_{ik} , $i = 1, 2, \dots, n_k$, $k = 1, 2$. Let

$$b_{hik} = \begin{cases} d_{ik} - \theta_h & h = L, U, \text{ for subjects in sequence 1} \\ d_{ik} & \text{for subjects in sequence 2.} \end{cases} \quad (21)$$

When there are no carryover effects, the expected value and variance of b_{hik} , where $h = L, U$, $i = 1, 2, \dots, n_k$, and $k = 1, 2$, are given by

$$E(b_{hik}) = \begin{cases} \frac{1}{2}[(P_2 - P_1) + (\theta - 2\theta_h)] & \text{for } k = 1 \\ \frac{1}{2}[(P_2 - P_1) - \theta] & \text{for } k = 2 \end{cases} \quad (22)$$

and

$$V(b_{hik}) = V(d_{ik}) = \sigma_d^2 = \sigma_e^2/2.$$

It can be seen that $E(b_{hi1}) - E(b_{hi2}) = (\theta - \theta_h) = \theta_h^*$.

Thus, for a fixed h , $\{b_{hi1}\}$ and $\{b_{hi2}\}$ have the same distribution except for the difference $(=\theta_h^*)$ in location of the true formulation effect. Here, the Wilcoxon–Mann–Whitney rank sum test^[61,62] for the unpaired two-sample location problem can be directly applied to test each of the two sets of hypotheses given above. Consider the first set of hypotheses that

$$H_{01} : \theta_L^* \leq 0 \quad \text{vs.} \quad H_{a1} : \theta_L^* > 0.$$

The Wilcoxon–Mann–Whitney test statistic can be derived based on $\{b_{Li1}\}$, $i = 1, 2, \dots, n_1$ and $\{b_{Li2}\}$, $i = 1, 2, \dots, n_2$. Let $R(b_{Lik})$ be the rank of b_{Lik} in the combined sample $\{b_{Lik}\}$, $i = 1, 2, \dots, n_k$, $k = 1, 2$. Also, let R_L be the sum of the ranks of the responses for subjects in sequence 1; that is,

$$R_L = \sum_{i=1}^{n_1} R(b_{Li1}).$$

Thus, the Wilcoxon–Mann–Whitney test statistic for H_{01} is given by

$$W_L = R_L - \frac{n_1(n_1 + 1)}{2}.$$

We then reject H_{01} if

$$W_L > w(1 - \alpha). \quad (23)$$

where $w(1 - \alpha)$ is the $(1 - \alpha)$ th quantile of the distribution of W_L . Similarly, for the second set of hypotheses that

$$H_{02} : \theta_U^* \geq 0 \quad \text{vs.} \quad H_{a2} : \theta_U^* < 0,$$

we reject H_{02} if

$$W_U = R_U - \frac{n_1(n_1 + 1)}{2} < w(\alpha), \quad (24)$$

where R_U is the sum of the ranks of $\{b_{Uik}\}$ for subjects in the first sequence. Hence, average bioequivalence is concluded if both H_{01} and H_{02} are rejected; that is,

$$W_L > w(1 - \alpha) \quad \text{and} \quad W_U < w(\alpha). \quad (25)$$

The expected values and variances for W_L and W_U under the null hypotheses H_{01} and H_{02} , when there are no ties, are given by

$$\begin{aligned} E(W_L) &= E(W_U) = \frac{n_1 n_2}{2}, \\ V(W_L) &= V(W_U) = \frac{1}{12} n_1 n_2 (n_1 + n_2 + 1). \end{aligned} \quad (26)$$

When there are ties among observations, average ranks can be assigned to compute W_L and W_U . In this case, however, the expected values and variances of W_L and W_U become

$$\begin{aligned} E(W_L) &= E(W_U) = \frac{n_1 n_2}{2}, \\ V(W_L) &= V(W_U) = \frac{1}{12} n_1 n_2 (n_1 + n_2 + 1 - Q), \end{aligned} \quad (27)$$

where

$$Q = \frac{1}{(n_1 + n_2)(n_1 + n_2 - 1)} \sum_{v=1}^q (r_v^3 - r_v),$$

where q is the number of tied groups and r_v is the size of the tied group v . Note that if there are no tied observations, $q = n_1 + n_2$, $r_v = 1$ for $v = 1, 2, \dots, n$, and $Q = 0$, then Eq. (27) is reduced to Eq. (26). Since W_L and W_U are symmetric about their mean $(n_1 n_2)/2$, we have

$$w(1 - \alpha) = n_1 n_2 - w(\alpha). \quad (28)$$

When $n_1 + n_2$, the total number of subjects, is large (say $n_1 + n_2 > 40$) and the ratio of n_1 and n_2 is close to 0.5, a large sample approximation using the standard normal distribution can be used to approximate for average biosimilarity testing; that is, we may conclude bioequivalence if

$$Z_L > z(\alpha) \text{ and } Z_U < -z(\alpha),$$

where $z(\alpha)$ is the α th quantile of a standard normal distribution and

$$Z_L = \frac{W_L - E(W_L)}{\sqrt{V(W_L)}} = \frac{R_L - \left[\frac{n_1(n_1 + n_2 + 1)}{2} \right]}{\sqrt{\frac{1}{12} n_1 n_2 (n_1 + n_2 + 1)}},$$

$$Z_U = \frac{W_U - E(W_U)}{\sqrt{V(W_U)}} = \frac{R_U - \left[\frac{n_1(n_1 + n_2 + 1)}{2} \right]}{\sqrt{\frac{1}{12} n_1 n_2 (n_1 + n_2 + 1)}}. \quad (29)$$

Note that the variances in Z_L and Z_U should be replaced with that given in Eq. (26) if these are ties.

POWER CALCULATION FOR SAMPLE SIZE

Since power analysis for sample size calculation for bio-similar studies is similar to that for bioequivalence studies, in this section, we will focus on power analysis for sample size calculation for bioequivalence studies. The statistical procedures and/or formulas for bioequivalence assessment for generic drug products can be directly applied to biosimilarity assessment for biosimilar products.

For bioequivalence trials, a traditional approach for sample size determination is to conduct a power analysis based on the 80/20 decision rule. This approach, however, is based on point hypotheses rather than interval hypotheses and therefore may not be statistically valid. Phillips^[63] provided a table of sample sizes based on power calculations of Schuirmann's two one-sided tests procedure using the bivariate noncentral t -distribution. However, no formulas are provided. An approximate formula for sample-size calculations was provided in the work of Liu and Chow.^[64] Under a standard 2×2 crossover design, assuming that $n_1 = n_2 = n$ and $\theta = \mu_T - \mu_R = 0$, the sample size required for achieving $1 - \beta$ power at the α level of significance under interval hypotheses testing (or Schuirmann's two one-sided tests procedure) can be obtained by solving the following equation:

$$n \geq 2 \left[t(\alpha, 2n - 2) + t(\beta/2, 2n - 2) \right]^2 \left(\frac{\hat{\sigma}_d}{\Delta} \right)^2,$$

where $\Delta = 0.2\mu_R$. If the ± 20 rule is used, then the above equation becomes

$$n \geq \left[t(\alpha, 2n - 2) + t(\beta/2, 2n - 2) \right]^2 \left(\frac{CV}{20} \right)^2$$

where $CV = 100 \times \sqrt{2\hat{\sigma}_d^2} / \mu_R$.

In the case where $\theta = \theta_0 \neq 0$, the sample size required for achieving $1 - \beta$ power at the α level of significance under Schuirmann's two one-sided tests procedure can be obtained by solving the following equation:

$$n(\theta_0) \geq 2 \left[t(\alpha, 2n - 2) + t(\beta/2, 2n - 2) \right]^2 \left(\frac{\hat{\sigma}_d}{\Delta - \theta_0} \right)^2,$$

where $\Delta = 0.2\mu_R$. If the ± 20 rule is used, then the above equation becomes

$$n(\theta_0) \geq \left[t(\alpha, 2n - 2) + t(\beta/2, 2n - 2) \right]^2 \left(\frac{CV}{20 - \theta'_0} \right)^2$$

where $\theta'_0 = 100 \times \theta_0 / \mu_R$.

For illustration purpose, Table 4 gives the total sample sizes needed to achieve a desired power for a standard crossover design for various combinations of $\theta = \mu_T - \mu_R$ and CV, where

$$CV = 100 \times \sqrt{2\hat{\sigma}_d^2} / \mu_R.$$

Table 4 Sample size requirements

Power (%)	CV (%)	$\theta = \mu_T - \mu_R$		
		0%	5%	10%
80	10	8	8	16
	14	10	14	26
	18	16	20	42
	22	24	28	62
	26	32	40	86
	30	40	52	114
	34	52	66	146
	38	64	82	180
	40	70	90	200
	40	70	90	200
90	10	10	10	20
	14	14	18	36
	18	20	28	58
	22	28	40	86
	26	40	54	118
	30	52	70	156
	34	66	90	200
	38	80	112	250
	40	90	124	276
	40	90	124	276

In practice, biosimilar studies often utilize higher order crossover designs such as Balaam's design, the two-sequence dual design, and four-period crossover designs with either two sequences or four sequences. A higher order crossover design is defined as a crossover design either whose number of sequences or whose number of periods is larger than the number of treatments to be compared. Sample size requirements for a higher order crossover design can be similarly obtained. Consider the following commonly used high-order crossover designs:

Design 1: Balaam's design—(TT, RR, RT, TR)

Design 2: Two-sequence, three-period dual design—(TRR, RTT)

Design 3: Four-period design with two sequences—(TRRT, RTTR)

Design 4: Four-period design with four sequences—(TTRR, RRTT, TRTR, RTTR)

Let n_i denote the number of subjects in each sequence i having the same value n , and F_v denote the cumulative distribution function of the t distribution with v degrees of freedom. Then the power function, $P_k(\theta)$, of Schuirman's two one-sided tests at the α nominal level for design k is given as follows^[65]:

$$P_k(\theta) = F_{v_k} \left(\left[\frac{\Delta - \theta}{CV \sqrt{\frac{b_i}{n}}} \right] - t(\alpha, v_k) \right) - F_{v_k} \left(t(\alpha, v_k) - \left[\frac{\Delta + \theta}{CV \sqrt{\frac{b_i}{n}}} \right] \right), \text{ for } k = 1, 2, 3, 4,$$

where $v_1 = 4n - 3$, $v_2 = 4n - 4$, $v_3 = 6n - 5$, $v_4 = 12n - 5$, $b_1 = 2$, $b_2 = 3/4$, $b_3 = 11/20$, $b_4 = 1/4$. Similarly, the sample size n required to achieve a $1 - \beta$ power at the α nominal level for each corresponding design k after the logarithmic transformation is determined by the following equations:

$$n \geq b_k \left[t(\alpha, v_k) + t\left(\frac{\beta}{2}, v_k\right) \right]^2 [CV/\ln(1.25)]^2 \text{ if } \delta = 1,$$

$$n \geq b_k \left[t(\alpha, v_k) + t(\beta, v_k) \right]^2 [CV/(\ln(1.25) - \ln \delta)]^2 \text{ if } 1 < \delta < 1.25,$$

and

$$n \geq b_k \left[t(\alpha, v_k) + t(\beta, v_k) \right]^2 [CV/(\Delta - \theta)]^2 \text{ if } 0.8 < \delta < 1.$$

where $\ln$ denotes the natural logarithm and $CV = \sqrt{\exp(\sigma^2) - 1}$, the coefficient of variation in the

multiplicative model, and σ^2 is the residual (within-subject) variance on the log scale. However, because the degrees of freedom are usually unknown, an easy way to find the sample size is to enumerate n .

UNIFIED APPROACH FOR ASSESSING BIOSIMILARITY

Chow^[66,67] proposed the development of a composite index for assessing the biosimilarity of follow-on biologics based on the facts that (1) the concept of biosimilarity for biologic products (made of living cells) is very different from that of bioequivalence for drug products, and (2) biologic products are very sensitive to small changes in the variation during the manufacturing process (i.e., it might have a drastic change in clinical outcome). Although some research on the comparison of moment-based criteria and probability-based criteria for the assessment of (1) average biosimilarity and (2) variability of biosimilarity for some given study endpoints by applying the criteria for bioequivalence is available in the literature (see, e.g., the works of Chow et al. and Hsieh et al.)^[68,69] universally acceptable criteria for biosimilarity are not available in the regulatory guidelines/guidances. Thus, Chow^[66] and Chow et al.^[70] proposed a biosimilarity index based on the concept of the probability of reproducibility as follows:

- Step 1. Assess the average biosimilarity between the test product and the reference product based on a given biosimilarity criterion. For illustration purposes, consider the bioequivalence criterion as a biosimilarity criterion. That is, biosimilarity is claimed if the 90% confidence interval of the ratio of means of a given study endpoint falls within the biosimilarity limits of (80.00%, 125.00%) or (−0.2231, 0.2231) based on raw (original) data or based on log-transformed data.
- Step 2. Once the product passes the test for biosimilarity in Step 1, calculate the reproducibility probability based on the observed ratio (or observed mean difference) and variability.^[71] Thus, the calculated reproducibility probability will take the variability and the sensitivity of heterogeneity in variances into consideration for the assessment of biosimilarity.
- Step 3. We then claim biosimilarity if the calculated 95% confidence lower bound of the reproducibility probability is larger than a prespecified number p_0 , which can be obtained based on an estimate of reproducibility probability for a study comparing a reference product to itself (the “reference product”). We will refer to such a study as an R–R study. We can then claim (local) biosimilarity if the 95% confidence lower bound of the biosimilarity index is larger than P_0 .

In an R–R study, define

$$P_{TR} = P \left(\begin{array}{l} \text{concluding average biosimilarity between the} \\ \text{test and reference products in a future trial,} \\ \text{given that the average biosimilarity based on} \\ \text{ABE criterion has been established in the} \\ \text{first trial} \end{array} \right) \quad (30)$$

A reproducibility probability for evaluating the biosimilarity of the same two reference products, based on the ABE criterion, is defined as follows:

$$P_{RR} = P \left(\begin{array}{l} \text{concluding average biosimilarity of the two} \\ \text{same reference products in a future trial, given} \\ \text{that the average biosimilarity based on ABE} \\ \text{criterion has been established in first trial} \end{array} \right) \quad (31)$$

Since the idea of the biosimilarity index is to show that the reproducibility probability for comparing “a reference product” with “the reference product” is higher in a study than the comparison of a follow-on biologic with the innovative (reference) product, the criterion of an acceptable reproducibility probability (i.e., p_0) for the assessment of biosimilarity can be obtained based on the R–R study. For example, if the R–R study suggests the reproducibility probability of 90%, i.e., $P_{RR} = 90\%$, the criterion of the reproducibility probability for bioequivalence study could be chosen as 80% of the 90% which is $p_0 = 80\% \times P_{RR} = 72\%$.

The biosimilarity index, described previously, has the advantages that (1) it is robust with respect to the selected study endpoint, biosimilarity criteria, and study design, and (2) the probability of reproducibility will reflect the sensitivity of heterogeneity in variance.

Note that the proposed biosimilarity index can be applied to different functional areas (domains) of biological products such as PK, biological activities, biomarkers (e.g., PD), immunogenicity, manufacturing process, and efficacy. An overall biosimilarity index or totality biosimilarity index across domains can be similarly obtained as follows:

Step 1. Obtain $\hat{p}_i$, the probability of reproducibility for the i -th domain, $i = 1, \dots, K$.

Step 2. Define the biosimilarity index $\hat{p} = \sum_{i=1}^K w_i \hat{p}_i$, where w_i is the weight for the i th domain.

Step 3. Claim global biosimilarity if we reject the null hypothesis that $p \leq p_0$, where p_0 is a prespecified acceptable reproducibility probability. Alternatively, we can claim (global) biosimilarity if the 95% confidence lower bound of p is larger than p_0 .

Let T and R be the parameters of interest (e.g., PK response) with means of μ_T and μ_R , for a test product and a reference product, respectively. Thus, the interval

hypotheses for testing the ABE of two products can be expressed as

$$H_0: \theta'_L \geq \frac{\mu'_T}{\mu'_R} \quad \text{or} \quad \theta'_U \leq \frac{\mu'_T}{\mu'_R} \quad \text{vs.} \quad H_a: \theta'_L < \frac{\mu'_T}{\mu'_R} < \theta'_U$$

where (θ'_L, θ'_U) is the ABE limit. For *in vivo* bioequivalence testing, (θ'_L, θ'_U) is chosen to be (80.00%, 125.00%). The above hypotheses can be reexpressed as

$$H_0: \theta_L \geq \mu_T - \mu_R \quad \text{or} \quad \theta_U \leq \mu_T - \mu_R \\ \text{vs.} \quad H_a: \theta_L < \mu_T - \mu_R < \theta_U$$

where μ_T and μ_R are the means of log-transformed data that are equal to the log-transformed values of μ'_T and μ'_R . (θ_L, θ_U) is $(-0.2231, 0.2231)$, which are equal to the log-transformed values of (80.00%, 125.00%). To calculate the reproducibility probability under the above interval hypotheses, the probability of P_{TR} can be expressed as the following when considering a parallel design, since it is a common design for biologic products:

$$P(\delta_L, \delta_U) = P \left(T_L(\bar{Y}_T, \bar{Y}_R, s_T, s_R) > t_{\alpha, dfp} \right. \\ \left. \text{and } T_U(\bar{Y}_T, \bar{Y}_R, s_T, s_R) < -t_{\alpha, dfp} \mid \delta_L, \delta_U \right) \quad (32)$$

where s_T , s_R , n_T , and n_R are the sample standard deviations and sample sizes for the test and reference formulations, respectively. The value of dfp can be calculated by

$$dfp = \frac{\left(\frac{s_T^2}{n_T} + \frac{s_R^2}{n_R} \right)^2}{\left(\frac{s_T^2}{n_T} \right)^2 + \left(\frac{s_R^2}{n_R} \right)^2}$$

$$T_L(\bar{Y}_T, \bar{Y}_R, \hat{\sigma}_T, \hat{\sigma}_R) = \frac{(\bar{Y}_T - \bar{Y}_R) - \theta_L}{\sqrt{\frac{s_T^2}{n_T} + \frac{s_R^2}{n_R}}}$$

$$T_U(\bar{Y}_T, \bar{Y}_R, \hat{\sigma}_T, \hat{\sigma}_R) = \frac{(\bar{Y}_T - \bar{Y}_R) - \theta_U}{\sqrt{\frac{s_T^2}{n_T} + \frac{s_R^2}{n_R}}}$$

$$\delta_L = \frac{\mu_T - \mu_R - \theta_L}{\sqrt{\frac{\sigma_T^2}{n_T} + \frac{\sigma_R^2}{n_R}}} \quad \text{and} \quad \delta_U = \frac{\mu_T - \mu_R - \theta_U}{\sigma_d \sqrt{\frac{\sigma_T^2}{n_T} + \frac{\sigma_R^2}{n_R}}} \quad (33)$$

σ_T^2 and σ_R^2 are the variances for test and reference formulations, respectively.

The vectors (T_L, T_U) can be shown to follow a bivariate noncentral t -distribution with $n_1 + n_2 - 2$ and dfp degrees of freedom, correlation of 1, and noncentrality parameters

of δ_L and δ_U .^[72,63] Owen^[72] showed that the integral of the above bivariate noncentral t -distribution can be expressed as the difference of the integral between two univariate noncentral t -distributions. Therefore, the power function in Eq. (33) can be obtained by

$$P(\delta_L, \delta_U) = Q_f(t_U, \delta_U; 0, R) - Q_f(t_L, \delta_L; 0, R) \quad (34)$$

where

$$Q_f(t, \delta; 0, R) = \frac{\sqrt{2\pi}}{\Gamma(f/2)2^{(f-2)/2}} \int_0^R G(tx/\sqrt{f} - \delta) x^{f-1} G'(x) dx$$

$$R = (\delta_L - \delta_U) \sqrt{f} / (t_L - t_U), \quad G'(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2},$$

$$G(x) = \int_{-\infty}^x G'(t) dt$$

and

$$t_L = t_{\alpha, dfp}, \quad t_U = -t_{\alpha, dfp} \quad \text{and} \quad f = dfp \quad \text{for parallel design.}$$

Note that when $0 < \theta_U = -\theta_L$, $P(\delta_L, \delta_U) = P(-\delta_U, -\delta_L)$.

The reproducibility probabilities increase when the sample size increases and the ratio of means is close to 1, while it decreases when variability increases for the same setting of sample size and means ratio. This shows the impact of variability on reproducibility probabilities. Since true values of δ_L and δ_U are unknown, using the idea of replacing δ_L and δ_U in Eq. (34) by their estimates based on the sample from the first study, the estimated reproducibility probability can be obtained as

$$\hat{P}(\hat{\delta}_L, \hat{\delta}_U) = Q_f(t_U, \hat{\delta}_U; 0, \hat{R}) - Q_f(t_L, \hat{\delta}_L; 0, \hat{R}) \quad (35)$$

where

$$\hat{\delta}_L = \frac{\bar{Y}_T - \bar{Y}_L - \theta'_L}{\sqrt{\frac{s_T^2}{n_T} + \frac{s_R^2}{n_R}}}, \quad \hat{\delta}_U = \frac{\bar{Y}_T - \bar{Y}_L - \theta'_U}{\sqrt{\frac{s_T^2}{n_T} + \frac{s_R^2}{n_R}}},$$

$$\hat{R} = (\hat{\delta}_L - \hat{\delta}_U) \sqrt{f} / (t_L - t_U)$$

CONCLUDING REMARKS

Biologic products or medicines are therapeutic agents made of a living system or organisms. As a number of biologic products will be due to expire in the next few years, the potential opportunity in developing the follow-on products of these originator products may result in the reduction of these products and provide more choices to medical doctors and patients for getting the similar treatment care with lower cost. However, the price reductions versus the originator biologic products remain to be determined, as the advantage of a slightly cheaper price may be outweighed by the hypothetical increased risk of side effects from biosimilar molecules that are not the exact copies of their originators. Unlike traditional small-molecule drug

products, the characteristics and development of biologic products are more complicated and sensitive to many factors. Any small change in the manufacturing process may result in the change of therapeutic effect of the biologic products. The traditional bioequivalence criterion for average bioequivalence of small-molecule drug products may not be suitable for evaluation of the biosimilarity of biologic products. Therefore, in this chapter, we evaluate the biosimilarity index proposed by Chow et al.^[70] for the assessment of the (average) biosimilarity between the innovator and reference products. Results based on both the estimation and Bayesian approaches demonstrate that the proposed method based on the biosimilarity index can reflect the characteristics and impact of variability on the therapeutic effect of biologic products. However, the estimated reproducibility probability based on the Bayesian approach depends on the choice of the prior distributions. If a different prior such as an informative prior is used, a sensitivity analysis may be performed to evaluate the effects of different prior distributions.

The other advantage is that the proposed method can be applied to different functional areas (domains) of biological products such as PK, biological activities, biomarkers (e.g., PD), immunogenicity, manufacturing process, and efficacy, since it is developed based on the probability of reproducibility. Further research will be employed for the development of the statistical testing approach for the evaluation of biosimilarity across domains.

Current methods for the assessment of bioequivalence for drug products with identical active ingredients are not applicable to follow-on biologics due to fundamental differences. The assessment of biosimilarity between follow-on biologics and innovator in terms of surrogate endpoints (e.g., PK parameters and/or PD responses) or biomarkers (e.g., genomic markers) requires the establishment of the Fundamental Biosimilarity Assumption in order to bridge the surrogate endpoints and/or biomarker data to clinical safety and efficacy.

Unlike conventional drug products, follow-on biologics are very sensitive to small changes in variation during the manufacturing process, which have been shown to have an impact on the clinical outcome. Thus, it is a concern whether current criteria and regulatory requirements for the assessment of bioequivalence for drugs with small molecules can be applied also to the assessment of biosimilarity of follow-on biologics. It is suggested that current, existing criteria for the evaluation of bioequivalence, similarity, and biosimilarity be scientifically/statistically evaluated in order to choose the most appropriate approach for assessing biosimilarity of follow-on biologics. It is recommended that the selected biosimilarity criteria should be able to address (1) the sensitivity due to small variations in both location (bias) and scale (variability) parameters, and (2) the degree of similarity that can reflect the assurance for drug interchangeability.

Under the established Fundamental Biosimilarity Assumption and the selected biosimilarity criteria, it is

also recommended that appropriate statistical methods (e.g., comparing distributions and the development of biosimilarity index) be developed under valid study designs (e.g., Design A and Design B described earlier) for achieving the study objectives (e.g., the establishment of biosimilarity at specific domains or drug interchangeability) with a desired statistical inference (e.g., power or confidence interval). To ensure the success of studies conducted for the assessment of biosimilarity of follow-on biologics, regulatory guidelines/guidances need to be developed. Product-specific guidelines/guidances published by EU EMA have been criticized for not having standards. Although product-specific guidelines/guidances do not help to establish standards for the assessment of biosimilarity of follow-on biologics, they do provide the opportunity for accumulating valuable experience/information for establishing standards in the future. Thus, numerical studies are recommended including simulations, meta-analysis, and/or sensitivity analysis, in order to (1) provide a better understanding of these product-specific guidelines/guidances and (2) check the validity of the established Fundamental Biosimilarity Assumption, which is the legal basis for assessing biosimilarity of follow-on biologics.

Abstract

This entry will review the issues surrounding biosimilars, including manufacturing, quality control, clinical efficacy, side effects (safety), and immunogenicity. In addition, it will also attempt to address the question regarding how regulatory agencies and industry regulations are evolving to deal with these issues.

INTRODUCTION

When an innovative (brand-name) drug product goes off patent, pharmaceutical and generic companies may file an abbreviated new drug application (ANDA) for approval of the generic copies of the innovative drug product. In 1984, the U.S. Food and Drug Administration (FDA) was authorized to approve generic drug products under the *Drug Price Competition and Patent Term Restoration Act* (which is also known as the *Hatch and Waxman Act*). For approval of generic drug products, the FDA requires that evidence in average of bioavailability (in terms of rate and extent of drug absorption) be provided through the conduct of bioavailability and bioequivalence studies. As indicated by Chow and Liu,^[1] the assessment of bioequivalence as a surrogate for evaluation of drug safety and efficacy is based on the *Fundamental Bioequivalence Assumption* that if two drug products are shown to be bioequivalent in average bioavailability, they will reach the same therapeutic effect or they are therapeutically equivalent. Under the Fundamental Bioequivalence Assumption, regulatory requirements, study design (e.g., a two-sequence, two-period crossover design or a replicated crossover design), criteria (e.g., 80/125 rule based on log-transformed data), and statistical methods (e.g., Shuirmann's two one-sided tests or confidence interval approach) for assessment of bioequivalence have been well established.^[1–4]

Unlike drug products, the concept for development of generic versions of biologic products, which are usually referred to as follow-on biologics (by the U.S. FDA) or biosimilars (by the European Medicine Agency [EMA] of the European Union) is different. Webber^[5] defines follow-on (protein) biologics as products that are intended to be sufficiently similar to an approved product to permit

the applicant to rely on certain existing scientific knowledge about safety and efficacy of an approved reference product. Under this definition, follow-on products are not only intended to be similar to the reference product, but also intended to be interchangeable with the reference product. As a number of biologic products are due to expire in the next few years, the subsequent production of follow-on products has aroused considerable interest within the pharmaceutical/biotechnological industry as biosimilar manufacturers strive to obtain part of an already large and rapidly growing market. The potential opportunity for price reductions versus the originator biologic products remains to be determined, as the advantage of a slightly cheaper price may be outweighed by the hypothetical increased risk of side effects from biosimilar molecules that are not exact copies of their originators. In this entry, we will focus on the issues surrounding biosimilars, including manufacturing, quality control, clinical efficacy, side effects (safety), and immunogenicity. In addition, we will also attempt to address the question regarding how regulatory agencies and industry regulations are evolving to deal with these issues.

Biosimilars are fundamentally different from generic chemical drugs. Important differences include the size and complexity of the active substance and the nature of the manufacturing process. Unlike classical generics, biosimilars are not identical to their originator products and therefore should not be brought to market using the same procedure applied to generics. This is partly a reflection of the complexities of manufacturing and safety and efficacy controls of biosimilars when compared to their small-molecule generic counterparts.^[6–9] Because biologic products are usually recombinant protein molecules manufactured in living cells,^[10] manufacturing processes for biologic products are

highly complex and require hundreds of specific isolation and purification steps. In practice, it is impossible to produce an identical copy of a biologic product, as changes to the structure of the molecule can occur with changes in the production process. Given that a protein can be modified (e.g., a side chain may be added, the structure may have changed due to protein misfolding, and so on) during the process, different manufacturing processes may invariably lead to structural differences in the final product, which may result in differences in efficacy and may have a negative impact on patient immune responses.

The remainder of this entry is organized as follows. The next section briefly outlines regulatory requirements for approval of biosimilars by the EMEA of the European Union as well as the current position of the FDA. The section “Criteria for Similarity” reviews various criteria for assessment of bioequivalence, similarity, and consistency that appeared in either regulatory guidances and/or literature. Some scientific issues for assessment of biosimilars are discussed in the section “Scientific Issues,” while the section “Assessing Similarity Using Genomic Data” proposes an approach for assessment of similarity using genomic data. The last section provides a brief concluding remark.

REGULATORY REQUIREMENTS

The EMEA^[11–19] has issued a new guideline describing general principles for the approval of similar biological medicinal products or biosimilars in the European Union. The guideline is accompanied by four concept papers that outline areas in which the agency intends to provide more targeted guidance. Specifically, the concept papers discuss approval requirements for four classes of human recombinant products containing erythropoietin, human growth hormone, granulocyte-colony stimulating factor, and insulin. The guidelines consist of a checklist of documents published to date relevant to data requirements for biological pharmaceuticals. It is not clear regarding what specific scientific requirements the guidelines will be applied to biosimilar applications, nor how the agency will treat innovator data contained in the reference product dossiers. Although the guidelines provide a useful summary of the biosimilar legislation and previous E.U. publications, it provides few answers to the issues.

On the other hand, approval of follow-on biologics in the United States depends on whether the biologic product is approved under the U.S. Food, Drug, and Cosmetic Act (U.S. FD&C) or whether it is licensed under the U.S. Public Health Service Act (U.S. PHS). As indicated, some proteins are licensed under the PHS Act, whereas others are approved under the FD&C Act. For products approved under a new drug application (NDA) (U.S. FD&C Act), generic version of the products can be approved under an ANDA, e.g., under Section 505(b)(2) of the FD&C Act.

For products that are licensed under a biologics license application (BLA) (U.S. PHS Act), there exists no abbreviated BLA. As pointed out by Woodcock et al.,^[20] for assessment of similarity of follow-on biologics, the FDA would consider the following factors: (i) the robustness of the manufacturing process, (ii) the degree to which structural similarity could be assessed, (iii) the extent to which mechanism of action was understood, (iv) the existence of valid, mechanistically related pharmacodynamic assays, (v) comparative pharmacokinetics, (vi) comparative immunogenicity, (vii) the amount of clinical data available, and (ix) the extent of experience with the original product.^[21–23] A typical example would be a recent regulatory approval of Omnitrope® (Somatropin), which was approved in 2006 under section 505(b)(2) of FD&C Act. Omnitrope® was approved based on the following evaluations: (i) physicochemical testing that established highly similar structure to Genotropin; (ii) new non-clinical pharmacology and toxicology data specific to Omnitrope®; (iii) pharmacokinetic (PK), pharmacodynamic (PD), and comparative bioavailability data; (iv) clinical efficacy and safety data from comparative controlled trials and from long-term trials with Omnitrope®; and (v) vast clinical experience and a wealth of published literature concerning the clinical effects (safety and effectiveness) of human growth hormone. The approval of Omnitrope® is based on an ad hoc case-by-case review of individual biosimilar application. In practice, there is a strong industrial interest and desire for the regulatory agencies to develop review standards and an approval process for biosimilars than an ad hoc case-by-case review of individual biosimilar applications. Along these lines, the FDA has indicated that the following guidances are currently under development: include (i) guidance for industry on scientific considerations in demonstrating the safety and effectiveness of follow-on protein products, and (ii) guidance for industry on chemistry, manufacturing, and control (CMC) issues for follow-on protein products.

CRITERIA FOR SIMILARITY

For comparison between drug products, some criteria for assessment of bioequivalence, similarity (e.g., dissolution profiles comparison), and consistency (e.g., comparison between manufacturing processes) are available in either regulatory guidelines/guidances and/or literature. These criteria, however, can be classified into (i) absolute change versus relative change, (ii) aggregated versus disaggregated, or (iii) moment-based versus probability-based. This section briefly reviews different categories of criteria.

Absolute Change Versus Relative Change

In clinical research and development, for a given study endpoint, post-treatment absolute change from baseline or post-treatment relative change from baseline is usually

considered for comparison between treatment groups. A typical example would be the study of weight reduction in obese patient population. In practice, it is not clear whether a clinically meaningful difference in terms of absolute change from baseline can be translated to a clinically meaningful difference in terms of relative change from baseline. Sample size calculation based on power analysis in terms of absolute change from baseline or relative change from baseline could lead to a very different result.

Current regulation for assessment of bioequivalence between drug products in terms of average bioavailability is based on relative change. In other words, we conclude (average) bioequivalence between a test product and a reference product if the 90% confidence interval for the ratio of means of the primary pharmacokinetic response such as area under the blood or plasma-concentration time curve (AUC) between the two drug products is totally within 80% and 125%. Note that regulatory agencies suggest that a log-transformation be performed before data analysis for assessment of bioequivalence.

Aggregated Versus Disaggregated

As indicated by Chow and Liu,^[1] bioequivalence can be assessed by evaluating differences in averages, intra-subject variabilities, and variance due to subject-by-formulation interaction between drug products *separately*. Individual criteria for assessment of differences in averages, intra-subject variabilities, and variance due to subject-by-formulation interaction between drug products are referred as to the disaggregated criteria. If the criterion is a single summary measure composed of these individual criteria, it is called the aggregated criterion.

For assessment of bioequivalence in average bioavailability (ABE), most regulatory agencies including the FDA recommend the use of disaggregate criterion based on average bioavailability. In other words, bioequivalence is concluded if the average bioavailability of the test formulation is within (80%, 125%) that of the reference formulation, with a certain assurance. Note that the EMEA^[24] and World Health Organization (WHO)^[25] use the same equivalence criterion of 80–125% for the log-transformed pharmacokinetic responses such as AUC. However, for Cmax, in certain cases, the EMEA and WHO allow a wider interval of 75–133% for the ratio of average bioavailability to address any safety and efficacy concerns for patients switched between formulations. If a wider interval is used, it must be pre-specified in the protocol. More details can be found in Chow and Liu.^[1]

On the other hand, for assessment of population bioequivalence (PBE) and individual bioequivalence (IBE), the following aggregated criteria are often considered. For assessment of individual bioequivalence, criterion proposed in the FDA guidance^[3] can be expressed as

$$\theta_I = (\delta^2 + \sigma_D^2 + \sigma_{WT}^2 - \sigma_{WR}^2) / \max\{\sigma_{W0}^2, \sigma_{WR}^2\}, \quad (1)$$

where $\delta = \mu_T - \mu_R$, $\sigma_{WT}^2, \sigma_{WR}^2, \sigma_D^2$ are the true difference in means, intra-subject variabilities of the test product and the reference product, and variance due to subject-by-formulation interaction between drug products, respectively. σ_{W0}^2 is the scale parameter specified by the user. Similarly, the criterion for assessment of population bioequivalence suggested in the FDA guidance^[3] is given by

$$\theta_p = (\delta^2 + \sigma_{TT}^2 - \sigma_{TR}^2) / \max\{\sigma_{T0}^2, \sigma_{TR}^2\}, \quad (2)$$

where $\sigma_{TT}^2, \sigma_{TR}^2$ are the total variances for the test product and the reference product, respectively and σ_{T0}^2 is the scale parameter specified by the user.

A typical approach is to construct a one-sided 95% confidence interval for $\theta_I(\theta_p)$ for assessment of individual (population) bioequivalence. If the one-sided 95% upper confidence limit is less than the bioequivalence limit of $\theta_I(\theta_p)$, we then conclude that the test product is bioequivalent to that of the reference product in terms of individual (population) bioequivalence. More details regarding individual and population bioequivalence can be found in Chow and Liu.^[1]

Moment Based Criteria Versus Probability Based Criteria

Schall and Luus^[26] propose the moment-based and probability-based measures for the expected discrepancy in pharmacokinetic responses between drug products. The moment-based measure suggested by Schall and Luus^[26] is based on the following expected mean-squared differences:

$$d(Y_j; Y_{j'}) = \begin{cases} E(Y_T - Y_R)^2 & \text{if } j = T \text{ and } j' = R \\ E(Y_R - Y_R')^2 & \text{if } j = R \text{ and } j' = R. \end{cases} \quad (3)$$

For some pre-specified positive number r , one of probability-based measures for the expected discrepancy is given as^[26]

$$d(Y_j; Y_{j'}) = \begin{cases} P\{|Y_T - Y_R| < r\} & \text{if } j = T \text{ and } j' = R \\ P\{|Y_R - Y_R'| < r\} & \text{if } j = R \text{ and } j' = R. \end{cases} \quad (4)$$

$d(Y_T; Y_R)$ measures the expected discrepancy for some pharmacokinetic metric between test and reference formulations, and $d(Y_R; Y_R')$ provides the expected discrepancy between the repeated administrations of the reference formulation. The role of $d(Y_R; Y_R')$ in formulation of bioequivalence criteria is to serve as a control. The rationale is that the reference formulation should be bioequivalent to itself. Therefore, for the moment-based measures, if the test formulation is indeed bioequivalent to the reference formulation, then $d(Y_T; Y_R)$ should be very close to $d(Y_R; Y_R')$. It follows that the criteria are functions of the difference (or ratio) between $d(Y_T; Y_R)$ and $d(Y_R; Y_R')$. Bioequivalence

is concluded if they are smaller than some pre-specified limit. On the other hand, for probability-based measures, if the test formulation is indeed bioequivalent to the reference formulation, as compared with $d(\mathcal{R}_R; \mathcal{Y}_R')$, $d(\mathcal{R}_T; \mathcal{Y}_R)$ should be relatively large. As a result, bioequivalence is assumed if the criteria based on the probability-based measure is greater than some pre-specified limit.

Similarity Factor for Dissolution Profile Comparison

In vivo bioequivalence studies are surrogate trials for assessing equivalence between test and reference formulations based on the rate and extent of drug absorption in humans to establish similar effectiveness and safety under the fundamental bioequivalence assumption. However, drug absorption depends on the dissolved state of drug product and dissolution testing provides a rapid *in vitro* assessment of the rate and extent of drug release. Leeson,^[27] therefore, has suggested that *in vitro* dissolution testing be used as a surrogate for *in vivo* bioequivalence studies to assess equivalence between the test and reference formulations for post-approval changes. For comparison of dissolution profiles, FDA guidance suggests considering the assessment of (i) the overall profile similarity and (ii) similarity at each sampling time point.^[28] In order to achieve these two objectives, based on Moore and Flanner,^[29] both the FDA scale-up and post-approval changes (SUPAC) guidance^[30] and guidance on dissolution testing^[28] suggest the similarity and difference factor for assessment of similarity. The similarity factor is then defined as the logarithm of the reciprocal square root transformation of 1 plus the mean-squared (the average sum of squares) difference in mean cumulative percentage dissolved between the test and reference formulations over all sampling time points. That is,

$$f_2 = 50 \log \left\{ \left[1 + \frac{Q}{n} \right]^{-0.5} 100 \right\}, \quad (5)$$

where

$$Q = \sum_{i=1}^n (\mu_{Ri} - \mu_{Ti})^2,$$

where log denotes the logarithm based on 10.

On the other hand, the difference factor is the sum of the absolute difference in mean cumulative percentage dissolved between the test and reference formulations divided by the sum of the mean cumulative dissolved of the reference formulation.

$$f_1 = \frac{\sum_{i=1}^n |\mu_{Ri} - \mu_{Ti}|}{\sum_{i=1}^n \mu_{Ri}} \quad (6)$$

It should be noted that the definitions of f_1 and f_2 provided by Moore and Flanner,^[29] and in the SUPAC and guidance on dissolution testing are not clear whether they are defined based on the population means or the sample averages. However, following the traditional statistical inference with ability for evaluation of error probability, we define both f_1 and f_2 based on the population mean dissolution rates. It follows that f_1 and f_2 are population parameters for assessment of similarity of dissolution profiles between the test and reference formulations.

Consistency in Manufacturing Process/Quality Control

Tse et al.^[31] have proposed a statistical quality control (QC) method to assess a proposed an index to test consistency between raw materials (which are from different resources) and/or between final products manufactured by different manufacturing processes. The consistency index is defined as the probability that the ratio of the characteristics (e.g., potency) of the drug products produced by two different manufacturing processes is within a pre-specified limit of consistency. The consistency index closes to 1 indicates that the characteristics of the drug products from the two manufacturing processes are almost identical. The idea for testing consistency is to construct a 95% confidence interval for the proposed consistency index under a sampling plan. If the constructed 95% confidence lower limit is greater than a pre-specified QC lower limit, then we claim that the final products produced by the two manufacturing processes are consistent.

Let U and W be the characteristics of the drug products from two different manufacturing processes, where $X = \log U$ and $Y = \log W$ follows normal distributions with means μ_X , μ_Y and variances V_X , V_Y , respectively. Similar to the idea of using $P(X < Y)$ to assess reliability in statistical quality control,^[32–33] Tse et al.^[31] have proposed the following probability as an index to assess the consistency between the two different manufacturing processes:

$$p = P\left(1 - \delta < \frac{U}{W} < \frac{1}{1 - \delta}\right),$$

where $0 < \delta < 1$ and is defined as a limit that allows for consistency. Tse et al.^[31] refer p as the consistency index. Thus p tends to 1 as δ tends to 1. For a given δ , if p is close to 1, materials U and W are considered to be identical. It should be noted that a small δ implies the requirement of high degree of consistency between material U and material W . In practice, it may be difficult to meet this narrow specification for consistency. Tse et al.^[31] have proposed the following quality control (QC) criterion: If the probability that the lower limit $LL(\hat{p})$ of the constructed $(1 - \alpha) \times 100\%$ confidence interval of p is greater than or equal to a pre-specified quality control lower limit, say, QC_L , exceeds a pre-specified number β (say $\beta = 80\%$), then we claim that

U and W are consistent or similar. In other words, U and W are consistent or similar if $P(QC_L \leq LL(\hat{p})) \geq \beta$, where β is a pre-specified constant.

SCIENTIFIC ISSUES

Biosimilarity in Biological Activity

Pharmacological or biological activity is an expression describing the beneficial or adverse effects of a drug on living matter. When the drug is a complex chemical mixture, this activity is exerted by the substance's active ingredient or pharmacophore but can be modified by the other constituents. The main kind of biological activity is a substance's toxicity. Activity is generally dosage-dependent, and it is not uncommon to have effects ranging from beneficial to adverse for one substance when going from low to high doses. Activity depends critically on fulfillment of the absorption, distribution, metabolism, and excretion (ADME) criteria.

Note that the new European Community (EU) *Pharmaceutical Review* legislation published on April 30, 2004, amended the EU community code on medicinal products to provide for the approval of biosimilars based on less preclinical and clinical data than had been required for the original reference product. The complexity of the protein and knowledge of its structure-function relationships determine the types of information needed to establish similarity.

Similarity in Size and Structure

In practice, various *in vitro* tests such as the assessments of the primary amino acid sequence, charge, and hydrophobic properties are performed to compare the structural aspects of biosimilars with their originator molecules. However, there are concerns about whether *in vitro* tests can be predictive of biological activity *in vivo*, due to the fact that there are significant differences in biological activity despite similarities in size and structure. Besides, it is difficult to assess biological activity adequately as few animal models are able to provide data that can be extrapolated for an accurate and reliable prediction of biological activity in human. Thus, controlled clinical trials remain the most reliable means of demonstrating similarity between a biosimilar molecule and the originator product in the clinic.

The Problem of Immunogenicity

Given that all biologic products are biologically active molecules derived from living cells and have the potential to evoke an immune response, immunogenicity is probably the most critical safety concern for assessment of biosimilarity of follow-on biologics. Common possible causes of immunogenicity include, but are not limited to,

(i) sequence differences between therapeutic protein and endogenous protein; (ii) non-human sequences or epitopes; (iii) structural alterations; (iv) storage conditions; (v) purification during the manufacturing process; (vi) formulation (e.g., surfactants, etc.); (vii) route, dose, and frequency of administration; and (viii) patient status, such as genetic background. Thus, the following questions are necessarily asked when assessing biosimilarity between biological products: (i) What is the immunogenic potential of the therapeutic protein? (ii) What is the impact of the generating antibodies to the self protein? (iii) What is the impact of immunogenicity in preclinical toxicity (e.g., pharmacokinetic levels and dose limiting toxicity)? (iv) What is the impact of immunogenicity of the therapeutic protein on safety? (v) What are the risk evaluation and mitigation strategy process required by regulatory agencies such as the FDA?

The immune responses to biologic products can lead to (i) anaphylaxis, (ii) injection site reactions, (iii) flu-like symptoms, and (iv) allergic responses. Note that one of the most serious adverse events occurs when neutralizing antibodies to product react with endogenous proteins that have a unique physiological role. The risk of immunogenicity can be reduced through stringent testing of the products during its development. However, it should be noted not only that immunogenicity in animals does not predict immunogenicity in the clinical trials, but also that analytical techniques may not detect changes that may impact immunogenicity. Therefore, the immunogenicity of a biological product depends heavily upon the product quality attributes such as the physical, structural, and functional properties of the active pharmaceutical ingredients as well as excipients, container closure, and delivery system. It turns out that similarity of the acceptable ranges of these quality attributes is crucial to the evaluation of equivalence between biosimilar and innovator's products.

Manufacturing Process

Unlike small-molecule drug products, biological products are made of living cell. Thus, manufacturing of biologic products is a very complicated process, which involves the steps of (i) cell expansion, (ii) cell production (in bioreactors), (iii) recovery (through filtration or centrifugation), (iv) purification (through chromatography), and (v) formulation. A small discrepancy at each step (e.g., purification) could lead to a significant difference in the final product, which might cause drastic change in clinical outcomes. Thus, process control and validation play an important role for the success of the manufacturing of biological products. In addition, because at each step (e.g., purification), different methods may be used at different biological manufacturing processes (within the same company or at different biotech companies), tests for consistency are necessarily performed. Note that at the step of purification, the following chromatography media or resin are commonly

considered: (i) gel filtration, (ii) ion exchange, (iii) hydrophobic interaction, (iv) reversed phase normal phase, and (v) affinity. Thus, at each step of manufacturing process, primary performance characteristics should be identified, control, and tested for consistency for process control and validation.

Statistical Considerations

Fundamental Biosimilarity Assumption

Because of complexity of the biosimilar products, unlike its chemical generics, although the EMEA approved Omnitrope® and Valtropin® in 2006 and the FDA approved Omnitrope® in 2006, both regulatory agencies required clinical equivalence trials. For example, the application documents of Valtropin® submitted to the EMEA consists of the following clinical evaluations:

- i. One pivotal bioequivalence study in healthy volunteers. ($n = 24$)
- ii. One phase-III pivotal clinical equivalence trial for efficacy and safety in children with growth hormone deficiency (GHD). ($n = 147$)
- iii. One phase-III trial for efficacy and safety in children with Turn syndrome (TS). ($n = 30$)
- iv. One phase-III trial for efficacy and safety in children with TS conducted in Korea. ($n = 60$)
- v. One phase-III trial for efficacy and safety in adults with GHD. ($n = 92$)

Therefore, substantial clinical information was required by both regulatory agencies for the approval of Valtropin® as compared to one pivotal bioequivalence study and possible one food interaction study required by the chemical generics. In fact, the amount of clinical information requested by the regulatory agencies is almost equivalent to a NDA or BLA of an innovator's biological products. Consequently, reduction of the price of the biosimilar products is severely limited and the affordability and accessibility of the biological products, including biosimilar products, for patients in need is seriously hampered.

However, similar to the chemical generic drug products, approval for the biosimilar drug products can be treated as the evaluation of post-approval changes (International Conference on Harmonization Q5E, 2005),^[23] and the post-approval change is the change of drug manufacturers. Therefore, if the biosimilar drug products and the corresponding innovator's biological products appear highly similar. In addition, based on the accumulated experience relevant information and data, minute differences observed in the product characteristics are expected to have no adverse effect of safety and efficacy profiles. In these circumstances, biosimilar drug products and an innovator's products can be considered similar. Therefore, except for the traditional pivotal bioequivalence study, no further data

from pivotal phase-III trials should be requested. However, the above statement is based on a crucial assumption that the at least one of the product characteristics are reliable predictors of the safety and efficacy profiles of the biological products. As a result, the Fundamental Biosimilarity Assumption (FBA) is

When a biosimilar product is claimed to be biosimilar to an innovator's product based on some well-defined product characteristics and is therapeutically equivalent provided that the well-defined product characteristics are validated and reliable predictors of safety and efficacy of the products.

For the chemical generic products, the well-defined product characteristics are the exposure measures for early, peak, and total portions of the concentration-time curve. The FBA assumes that the equivalence in the exposure measures implies therapeutically equivalent. However, due to the complexity of the biosimilar drug products, one has to verify that some validated product characteristics are indeed reliable predictors of the safety and efficacy. It follows that the design and analysis for evaluation of equivalence between the biosimilar drug product and an innovator products are substantially different from those of the chemical generic products.

Study Design

Because some of the biological products such as therapeutic antibody or pegylated proteins have a long half-life, equivalence in terms of absorption/bioavailability may not be sufficient. Demonstration of equivalence on clearance and half-life may be required for assess the risk of difference in elimination rate. As a result, the traditional crossover designs may not be optimal for evaluation of equivalence between follow-on or biosimilar and innovator biological products. On the other hand, if the well-defined and validated product characteristics are pharmacokinetic/pharmacodynamic (PK/PD) responses, it is then very important to investigate the extrapolation ability of equivalence in PK responses to equivalence in PD, and to equivalence in efficacy responses. In order to ensure the internal validity of treatment comparisons, PK, PD, and efficacy response should be evaluated simultaneously in the same trials. We consider Design (a) in Fig. 1 proposed below:

Design (a) is a two-group parallel design in patients for the PKPD/efficacy bridging study with the disease which the innovator biological product indicates for. After meeting the inclusion and exclusion criteria, patients are randomly divided into two groups. PD/efficacy/safety will be evaluated for the first group of the patients (validation set). Additional PK responses will be assessed for the second group of the patients (training set). A randomization in a 1:1 ratio will be performed separately for each group. The sample size of the second group will be large enough to

Fig. 1 Diagram of PK/PD/efficacy bridging study

provide sufficient power for evaluation of bioequivalence based on PK responses. Calibration models will be built based on the PK/PD/efficacy response obtained from the patients in the training set. The PD/efficacy data from the validation set will be used to provide independent assessment of extrapolation ability of equivalence in PK responses to equivalence in PD/efficacy responses.

Design (a) may require quite large sample size because of simultaneously evaluation of extrapolation ability of equivalence in PK to equivalence in PD and to equivalence in efficacy. One way to resolve this issue is to adopt the design for dose-response trials for evaluation of extrapolation ability of equivalence in some well-defined product characteristics to equivalence in efficacy. This design is referred to as Design (b) shown in Fig. 2. Design (b) in fact consists of two dose-response trials: one for the biosimilar product and one for the innovator’s biological product, each with at least three dose levels with a placebo group. Eligible patients are first randomized into biosimilar or innovator groups. Within each group, patients are randomized again to receive

one of the doses for the respective products. Well-defined product characteristics and primary efficacy endpoints are evaluated for all patients at their respective doses. Suppose that a statistically significant relationship as represented by a simple linear regression equation can be established between the well-defined product characteristics and the primary efficacy endpoint through dose levels for the innovator’s product, perhaps after a suitable transformation. If a similar linear relationship can be also obtained for the biosimilar product, and its corresponding linear regression equation is very close to the one for the innovator’s product, then equivalence in efficacy based on the primary efficacy endpoint may be claimed. Because the innovator’s product has been approved by the regulatory agencies due to its confirmed efficacy, therefore the objective of Design (b) is not to establish the efficacy of either biological products but to establish the similar patterns of the relationship between the well-defined product characteristics and primary efficacy endpoint for the two products. As a result, the sample size of Design (b) can be reduced significantly.

Fig. 2 Design (b) for evaluation of extrapolation ability

Alternative Criteria for Biosimilarity

Due to the complexity, heterogeneity, and complication mechanisms of biological drug products, difference in variability between biosimilar and innovator biological products in PK, PD, and clinical responses will be much larger than the difference observed between the conventional generic and innovator chemical drug product. Therefore, average bioequivalence alone is not sufficient to establish equivalence between the follow-on and innovator biological products. On the other hand, because of the masking effect, the aggregate metrics for population and individual bioequivalence fail to address the closeness of the distributions of the responses between the follow-on and innovator biological products.^[34,35] Disaggregate metrics can address the masking effect suffered by the aggregate metrics and find the sources of inequivalence. However, determination of individual equivalence margins with different interpretation is not an easy task. In addition, because of multi-parameters involved, any procedures based on disaggregate metric for evaluation of equivalence between follow-on and innovator biological products will tend to be conservative, especially in the small samples. Furthermore, all current methods derived from the probability-based, moment-based, aggregate, or disaggregate criteria are based on the normality assumption that is either extremely difficult to verify or simply not true. To resolve the above-mentioned dilemmas for evaluation of equivalence, the following concept of stochastic equivalence or stochastic non-inferiority is proposed.

Let $F(x)$ and $G(y)$ be the cumulative distribution functions of the responses for biosimilar and innovator biological products, respectively. Assuming that a large response value indicates a better efficacy, the follow-on and innovator biological products are said to be stochastically equivalent (two-sided) if the absolute difference between $F(x)$ and $G(x)$ is within some pre-specific margins for all x . In other words, metric $\theta = \sup|F(x) - G(x)|$ and hypothesis for equivalence becomes

$$\begin{aligned} H_0 : \sup|F(x) - G(x)| \geq \eta, \text{ for some } x \\ \text{vs.} \\ H_1 : \sup|F(x) - G(x)| < \eta, \text{ for all } x \end{aligned} \quad (7)$$

Similarly, the biosimilar product is said to be stochastically non-inferior to the innovator counterpart if the difference between $F(x)$ and $G(x)$ is greater than $-\eta$. The corresponding hypothesis is given as

$$\begin{aligned} H_0 : \sup[F(x) - G(x)] \leq -\eta, \text{ for some } x \\ \text{vs.} \\ H_1 : \sup[F(x) - G(x)] > -\eta, \text{ for all } x \end{aligned} \quad (8)$$

However, the hypotheses in Eq. (7) and Eq. (8) can only be used for evaluation of equivalence with respect to one study endpoint such as AUC or some primary efficacy endpoint. They cannot be utilized to assess whether the equivalence in product characteristics such as AUC can be extrapolated to equivalence in primary efficacy endpoints. Both well-defined product characteristics and primary efficacy endpoints are measured for each patient. Therefore, group means of well-defined product characteristic can be computed for each dose level for biosimilar and innovator's product respectively. Using the group means of the well-defined characteristic as the independent variable, a simple linear regression equation can be fit to the primary efficacy endpoint (dependent variable) for biosimilar and innovator's biological products respectively. It follows that the concept of the relative potency in the parallel-line bioassay can be then employed to investigate extrapolation ability of equivalence in product characteristic to equivalence in efficacy.^[36] In other words, if the relative potency between the biosimilar and innovator's biological products is within some predefined margins, then it can be concluded that equivalence in product characteristic be extrapolated to equivalence in efficacy. Fig. 3 depicts the application of the parallel line assay to evaluation of the extrapolation ability of equivalence in product characteristic to equivalence in efficacy. Let ρ be the relative potency of the biosimilar product to the innovator's biological product. The hypothesis of extrapolation ability is given below:

$$H_0 : \rho \leq \rho_L \text{ or } \rho \geq \rho_U \quad \text{vs} \quad H_A : \rho_L < \rho < \rho_U, \quad (9)$$

where $0 < \rho_L < 1 < \rho_U$.

Statistical Methods

Although the methods based on Kolmogorov-Smirnov type of statistics have extensively investigated,^[37] relatively little literature exists on the statistical tests for

Fig. 3 Parallel line assays to evaluation of extrapolation ability

stochastic equivalence or non-inferiority. One method is to employ the naïve asymptotic confidence band for $\theta = \sup|F(x) - G(x)|$ or $\theta = \sup[F(x) - G(x)]$ as the test statistics for hypotheses Eq. (7) and Eq. (8). If the $(1-2\alpha)100\%$ confidence band is totally contained with the band formed by the equivalence margins $(-\eta, \eta)$, then equivalence between the biosimilar and biological products can be concluded at the α significance level. Similarly, if the $(1-\alpha)100\%$ lower confidence band is above lower band formed by the lower margin $-\eta$, then non-inferiority of biosimilar product to the innovator's biological product can be established at the α significance level. Derivation of the test statistics for hypotheses in Eq. (7) and Eq. (8) at the boundary margins of the null hypothesis and the corresponding distribution and confidence interval require further research. However, permutation and bootstrap technique can also be used to find the distribution of the test statistics and the corresponding confidence intervals empirically.

Because of the nature of Design (a) proposed above, it is in fact an active control trial without a placebo control arm where the follow-on biological product is the test treatment, and its innovator counterpart is the active control treatment. Assuming that the innovator biological product was approved due to its superior efficacy over placebo, the equivalence in PD/efficacy is in fact the equivalence in relative efficacy as compared to the (putative) placebo of the follow-on biological product with the innovator counterpart. On the other hand, the prior information of the comparison of the innovator biological product to the placebo can be incorporated into determination of equivalence margins and the evaluation of equivalence between the follow-on and innovator biological products. The Bayesian design proposed by Simon^[38] may be applied to derive the procedures for assessment of equivalence based on PD/efficacy endpoints.

Calibration models have been used to correlate the surrogate responses with the true endpoints.^[39] Because PK, PD, and efficacy responses are random variables, mixed models was suggested to assessing surrogates as trial endpoints.^[40] The measurement error models can be used to establish calibration models.^[41] With the established calibration model obtained from the data of the training set of Design (a),

$$P_{\text{efpk}} = \Pr(\text{equivalence in efficacy responses} | \text{equivalence in PK responses})$$

and

$$P_{\text{pdpk}} = \Pr(\text{equivalence in PD responses} | \text{equivalence in PK responses})$$

will be estimated for evaluation extrapolation ability of the PK responses using the data from the validation set of Design (a). If P_{efpk} is sufficiently high, then the equivalence in PK responses can be extrapolated to the equivalence in

efficacy, then no further phase III clinical evaluation of biosimilar product based on efficacy responses may not be required. On the other hand, if P_{efpk} is low, then equivalence in PK responses cannot predict the equivalence in efficacy responses and phase III clinical trials for evaluation of follow-on biological product is required. Under Design (a), sample size required for the bioequivalence evaluation based on PK responses of the training set may be different for that the validation set for assessment of extrapolation. It is of interest to compare the sample size required by Design (a) to the total sample size required for the full clinical evaluation of biosimilar product.

For Design (b), the standard statistical method for analysis of parallel line assays can be used to construct the $(1-2\alpha)100\%$ confidence interval for the relative potency in the following steps:

- Step 1: Fit a linear regression equation to the primary efficacy endpoint with the group mean of the product characteristic at each dose level as the independent variable separately for the biosimilar and innovator's biological products. This may be done after a suitable transformation.
- Step 2: If the estimate of the slope of any one product is not significant at the predefined level, then one must conclude that no simple relationship can be established between the product characteristic and the primary endpoint and hence, a full clinical evaluation of the biosimilar product is required. Otherwise, go to Step 3.
- Step 3: Test whether the two estimated simple linear regressions are parallel at the predefined significance level. If the two estimated linear regressions are not parallel, then further clinical evaluation of the biosimilar product is warranted. Otherwise, proceed to Step 4.
- Step 4: Compute estimated relative potency and its corresponding $(1-2\alpha)100\%$ confidence interval. If the $(1-2\alpha)100\%$ confidence interval for the relative potency is within the predefined margins (ρ_L, ρ_U) , then equivalence in the product characteristic can be extrapolated to equivalence in the primary efficacy endpoint at the α significance level. Otherwise, further clinical investigation of the biosimilar product is needed.

The objective of application of Design (b) is not to establish the efficacy of biosimilar product but rather to test whether the relative potency is within some predefined limits. Therefore the required sample size for Design (b) is determined upon the test for positive slope and equivalence margins. Therefore, the sample size required by Design (b) may be fewer than that of Design (a) or of the full clinical evaluation of biosimilar product. However, further theoretical work or simulation studies are needed to address this issue.

ASSESSING SIMILARITY USING GENOMIC DATA

Although factors such as age, gender, education, socioeconomic status, smoking habit, weight, sexual orientation, and underlying disease characteristics at the baseline may contribute to the variation among patients, one of the most important reasons is the genetic or genomic variations among trial participants. As a result, due to genetic variations and genetic-by-environmental interaction, patients respond differently to the same treatment or therapeutic regimen. After completion of the Human Genome Project, the disease targets at the molecular level can be identified and hence biochip products based on heritable DNA markers, mutations, and expression patterns for detection of diseases using the microarray technology is possible. Genomic technologies such as DNA sequencing, mRNA transcript profiling, and comparative genomic hybridization have increased the possibility of identifying those patients who are most likely to benefit from a molecularly targeted drug, and this also indicates an increasing importance of diagnostic tests for identification of molecular targets and an increasing demand for targeted clinical trials conducted for the individualized treatment of patients. A new generation of molecularly targeted agents has been developed and approved by regulatory agencies such as the FDA and EMEA. Many of these drugs benefit only a subset of treated patients and may be overlooked by the traditional, broad-eligibility approach to randomized clinical trials. A major portion of targeted drugs are biological products. It follows that evaluation of biosimilar products should take into account the genomic information. Chow et al.^[42] proposed methods for evaluation bioequivalence using genomic data. Although their methods were derived for the chemical generics, the same principles can be applied to evaluation of biosimilar products. Similarly, the genomic information can be incorporated into the linear regression equations as possible covariates to reduce the variability for estimation and inference about the relative potency.

Because biological products are peptides or protein products with primary, secondary, tertiary, and quaternary structures, immunogenicity is an extremely important safety issue. On the other hand, unlike chemical generic products, no two biological products are exactly the same, even for the different batches of any innovator's product. It follows that evaluation of immunogenicity of biosimilar product is more important and difficult than chemical generic products and usually requires large clinical trials. However, identification of potential immunodominant positions and prediction of antigenic variants may provide a way to evaluation of immunogenicity of biosimilarity product without extensive clinical immunogenicity trials.^[43,44] Because the linear sequence of the primary structure usually determines the tertiary structure, one can conduct pairwise comparisons between the amino acid sequences

of the biosimilar product with those of the innovator's biological product and use the antigenic distance as a measure for evaluation of the similarity of the amino acid sequences between the biosimilar and innovator's products. If the potential antigenic sites of the amino acid sequences are known predictors of antigenic variants, this information along with other data can be used for equivalence evaluation of the amino acid sequences between the biosimilar and innovator's biological products. The cut-off margin based on the antigenic distance is 4, as recommended by Lee and Chen.^[45] However, more stringent margin could be applied if the potential antigenic sites are known to induce serious immunogenicity reactions.

CONCLUDING REMARKS

Because of the size and complexity of the active ingredients and the nature of manufacturing process, biological products are different from the traditional chemical drugs with small molecular weights. Many have pointed out that no two biological products are the same.^[6,9] It is also important to know that traditional chemical generics are not exact the same as their corresponding innovator's product either. They are different in the excipients and their compositions and manufacturing methods and processes. In addition, no two batches of the same innovator's biological products are the same. This is why International Conference on Harmonization (ICH) issued Q5E Guideline on Comparability of Biotechnological/Biological Products Subject to Changes in their Manufacturing Process^[46] issued in 2005 to address these issues the post-approval changes. The same principles for evaluating the post-approval changes for the innovator's biological products can and should be also applied to assess the similarity between the biosimilar and innovator's biological products because the change is the manufacturers of the product.

Under the authorization of the Drug Price Competition and Patent Restoration Act (Hatch-Waxman Act), in 1984 the FDA started to approve traditional chemical generic drug products through the ANDA process. Although at the beginning of the implementation of Hatch-Waxman Act there were serious concerns about whether the chemical generic products could deliver equivalent efficacy and safety, experience accumulated over the past 25 years indicates that the fundamental bioequivalence assumption is a sound basis for approval chemical generic products without conducting costly and time-consuming clinical trials. However, no similar legislation has been passed in the United States or the European Union to address those biological products that are much more expensive than the traditional chemical drug products. Therefore, approval of biosimilar products in Europe is based on some lower-ranking guidance that fails to provide specific scientific requirements. Approvals of Valtropin® and Omnitrope® by the FDA and the EMEA require the long-term clinical and safety data

obtained from multi-county, multi-center randomized clinical trials. These two applications are in fact two full-blown NDAs. Therefore, reduction in price for Valtropin® and Omnitrope® is very limited. Furthermore, due to the requirement of costly and long-term clinical trials, accessibility of biosimilar products to the needed patients is unnecessarily and severely delayed. It hopes that both the U.S. Congress and the E.U. Parliament can pass the necessary legislation required for approval of biosimilar products.

One key scientific issue is the search for product characteristics that are strongly correlated with efficacy, immunogenicity, and safety so that the fundamental biosimilar assumption can be verified. The crucial statistical methodology that should be rapidly developed is to evaluate the extrapolation ability from equivalence in product characteristics to equivalence in efficacy or immunogenicity. Until the above issues are satisfactorily and adequately addressed, biosimilar products will be still approved on an individual basis in accordance with the requirement of clinical data without any possibility of reducing price and increasing patients' accessibility.

Bivariate Zero-Inflated Poisson Populations: Statistical Test for Homogeneity

Siu-Keung Tse and Hak-Keung Yuen

Department of Management Sciences, City University of Hong Kong, Hong Kong, China

Abstract

The theme of this entry is on the discussion of the testing of treatment difference in the occurrence of a study end point. In particular, a randomized parallel-group comparative clinical trial with repeated responses under the assumption that the responses follow a bivariate zero-inflated Poisson (ZIP) distribution is considered. Result based on likelihood ratio test for homogeneity of two bivariate ZIP populations is presented. Approximate formula for sample size calculation is also obtained, which achieves a desired power for detecting a clinically meaningful difference under an alternative hypothesis. An example concerning the comparison of treatment effect in an addictive clinical trial in terms of the number of days of illicit drug use during a month is given for illustration purpose.

Keywords: Bivariate ZIP model; Erosion counts; Likelihood ratio test; Repeated responses; Sample size calculation.

INTRODUCTION

In clinical trials, the occurrence of certain events is commonly used as a surrogate end point for assessment of clinical outcomes (safety and/or efficacy) of a test treatment under the assumption that the surrogate end point is predictive of clinical outcomes. Commonly considered occurrences of certain events in clinical trials include, but are not limited to, the number of tumors observed during the course of the study in cancer trials, the number of erosions seen in gastrointestinal (GI) studies, the number of days of antibiotic use in infectious diseases (ID) clinical trials (which is an indication of efficacy), and the number of days of illicit drug use in addictive drug abuse trials (which is predictive of the treatment effect on addiction of drug abuse). These counts are usually considered as markers for predictive of clinical outcomes (i.e., safety and/or efficacy), if they are not directly related to clinical outcomes. For example, the number of tumors in cancer trials could be an indication of metastasis of the cancer. A large number of erosions most likely will lead to gastroduodenal ulcers and consequently serious GI toxicity (which is considered as adverse events for safety concern). The reduction of the number of days of antibiotic use is an indication of efficacy of the test treatment for treating certain infections. A small percent of illicit drug use is an indication of recovery from the addiction of drug abuse.

These counts are usually assumed to follow a Poisson distribution and can be based to assess whether there is any difference in mean counts between treatment groups. However, these counts could include a large proportion of zeros, and the proportion of zeros could be as high as 60%

in practice. Thus, a Poisson model may not be able to provide a good fit to the data. To accommodate this unusually large proportion of zeros, a zero-inflated Poisson (ZIP) model can be used for an accurate and reliable assessment of the treatment effect.

ZIP model has been used commonly to model the occurrence of unusually large number of zeros. Neyman^[1] and Feller^[2] first introduced the concept of zero-inflation to address the problem of excess zeros. Since then, there have been extensive studies related to the development of ZIP modeling. Van den Broek^[3] discussed the test of zero-inflation and proposed to use the Rao's score test for hypotheses testing. A simulation study was conducted to show that the score test was appropriate. Properties and inference of the ZIP distribution, including the maximum likelihood estimates (MLEs) of the parameters, can be found in the study by Gupta, Gupta and Tripathi.^[4] A review of the related literature was given in the study by Böhning^[5] and examples from different disciplines were also discussed. Bayesian analysis of ZIP can be found in the study by Angers and Biswas.^[6] Furthermore, Lambert;^[7] Böhning et al.;^[8] Dobbie and Welsh;^[9] and Lee, Wang, and Yau^[10] discussed the examples of ZIP regression model under various settings. More specifically, Jansakul and Hinde^[11] modified the score test to the regression case where the zero-mixing probability is dependent on covariates. A review of published works on the standard ZIP model can be found in Lee et al.,^[12] which also discussed the use of a multilevel ZIP regression model incorporating random effects to account for the data dependence arising from repeated measures or longitudinal studies.

For the comparison of two ZIP models, Lachenbruch^[13,14] discussed the hypotheses testing of two two-part models, where the framework incorporated the comparison of two ZIP models. In particular, these studies compared the size, the power, and the required sample size to achieve a desired power for several methods including the t-test and the Wilcoxin–Mann–Whitney rank sum test. Given two ZIP models, there are three possible scenarios: 1) there is no difference between treatments in the group of zeros; 2) there is no difference between treatments in the group of non-zeros; and 3) there are no differences between treatments in both groups of zeros and non-zeros. Tse et al.^[15] assumed that these counts follow a ZIP distribution and test the null hypothesis that there is no treatment difference in mean counts between treatment groups at the end of the study. Under a ZIP distribution, Tse et al.^[15] derived valid statistical tests under the above three possible scenarios.

However, their tests focus on the assessment at the end of the study and ignore the treatment effect during the process. In practice, multiple assessments are often considered to monitor the performance of the test treatment under investigation to determine when the test treatment will achieve the optimal therapeutic effect prior to the end of the treatment duration. Majumdar and Gries^[16] discussed a Bayesian approach to model bivariate count data with excess zeros. They used simulations to compare the performance of their Bayesian and classical ZIP approaches based on regression models. These models do not give a direct way to derive the required sample size to achieve a desired power for detecting a clinically meaningful difference under an alternative hypothesis. However, in many clinical applications, outcomes with unusually large number of zeros are often taken repeatedly on the same individual. These repeated outcomes certainly possess a certain correlated structure and analysis using univariate ZIP models would produce misleading conclusion, since the correlated structure is not properly addressed in the analysis process. Thus, there is a need to motivate the search of proper multivariate ZIP (MZIP) model to model these data. Early results on the discussion of MZIP model can be found in the study by Skellman,^[17] which are based on the idea of extending the univariate Poisson binomial distribution to a compound distribution of the binomial and the Poisson. Li et al.^[18] discussed several other ways to construct MZIP distribution and presented real-life applications of the MZIP in equipment-fault detection. However, as inherent in all multivariate distributions, the number of model parameters would increase rapidly in order to describe the covariance structure of the multivariate observations as the dimension increases. Large number of model parameters not only requires a large number of observations but also imposes difficulty in the estimation of the model parameters. Therefore, it is desirable to choose a MZIP model such that the corresponding number of model parameters is in a manageable size.

Yuen, Chow, and Tse^[19] proposed a bivariate model with five parameters and derived valid statistical test

for assessment of treatment effect, which takes multiple assessments into consideration. In particular, they proposed a bivariate ZIP model to compare the effects of two treatments in a two-armed clinical trial and derived approximate formula to determine the required sample size to achieve a desired power for two given bivariate ZIP models.

This entry aims to summarize the results developed by Yuen, Chow, and Tse.^[19] In the next section, a bivariate ZIP model with five parameters is presented and the corresponding notations are given in details. Results of the likelihood ratio test under a randomized parallel-group design comparing a test treatment with a control assuming that the responses follow a bivariate ZIP distribution are given in section “Likelihood Ratio Tests for the Comparison of Treatments.” The section “Determination of Sample Size” presents an approximate formula for sample size calculation which achieves a desired power for detecting a clinically meaningful difference at a prespecified level of significance. To illustrate the application of the results, section “An Example” presents an example concerning the comparison of randomization effects in terms of the number of days using illicit drug during a month is given for illustration purpose. Some concluding remarks are given in the section “Conclusion.”

A BIVARIATE ZIP MODEL

A bivariate ZIP (Y_1, Y_2) can be constructed from a mixture of a point mass at $(0, 0)$, two univariate Poisson distributions with parameters λ_1 and λ_2 , and a bivariate Poisson distribution with parameters $(\lambda_{10}, \lambda_{20}, \lambda_{00})$ as follows:

$$\begin{aligned} (Y_1, Y_2) &\sim (0, 0), && \text{with probability } p_0 \\ &\sim (\text{Poisson}(\lambda_1), 0), && \text{with probability } p_1 \\ &\sim (0, \text{Poisson}(\lambda_2)), && \text{with probability } p_2 \\ &\sim \text{bivariate Poisson}(\lambda_{10}, \lambda_{20}, \lambda_{00}), && \\ &&& \text{with probability } p_3 = 1 - p_0 - p_1 - p_2 \end{aligned} \quad (1)$$

Let $\lambda_1 = \lambda_{10} + \lambda_{00}$ and $\lambda_2 = \lambda_{20} + \lambda_{00}$. The probability function of the bivariate ZIP (Y_1, Y_2) is given as:

$$\begin{aligned} P(Y_1 = 0, Y_2 = 0) &= p_0 + p_1 \exp(-\lambda_1) + p_2 \exp(-\lambda_2) \\ &\quad + p_3 \exp(-\lambda_{10} - \lambda_{20} - \lambda_{00}) \\ P(Y_1 = y_1, Y_2 = 0) &= [p_1 \lambda_1^{y_1} \exp(-\lambda_1) + p_3 \lambda_{10}^{y_1} \exp(-\lambda_{10} - \lambda_{20} - \lambda_{00})] / y_1! \\ P(Y_1 = 0, Y_2 = y_2) &= [p_2 \lambda_2^{y_2} \exp(-\lambda_2) + p_3 \lambda_{20}^{y_2} \exp(-\lambda_{10} - \lambda_{20} - \lambda_{00})] / y_2! \\ P(Y_1 = y_1, Y_2 = y_2) &= p_3 \sum_{j=0}^{\min(y_1, y_2)} \lambda_{10}^{y_1-j} \lambda_{20}^{y_2-j} \lambda_{00}^j \frac{\exp(-\lambda_{10} - \lambda_{20} - \lambda_{00})}{(y_1 - j)! (y_2 - j)! j!} \end{aligned} \quad (2)$$

It should be noted that the marginal distribution of Y_1 is a univariate ZIP which is a mixture of point mass at 0 with probability $p_0 + p_2$ and a Poisson distribution with parameter λ_1 with probability $1 - (p_0 + p_2)$; similarly, Y_2 is a mixture of point mass at 0 with probability $p_0 + p_1$ and a Poisson distribution with parameter λ_2 with probability $1 - (p_0 + p_1)$. Furthermore, in many applications, Y_1 and Y_2 can be assumed to be identically distributed, i.e., $\lambda_1 = \lambda_2$. To simplify notations, let $\lambda_1 = \lambda_2 = \lambda$, then $\lambda_{10} = \lambda_{20} = \lambda_0$ and $\lambda_{00} = \lambda - \lambda_0$. Thus, λ , λ_0 , p_0 , p_1 , and p_2 are the parameters required in defining the model.

Suppose that a clinical study is conducted to compare the effect between a test treatment (T) and a control treatment (C). Assume that n_T and n_C subjects are randomly assigned to the test treatment and control treatment, respectively. Let (Y_{iC1}, Y_{iC2}) be the observed responses corresponding to the i^{th} subject in the control treatment group, $i = 1, 2, \dots, n_C$. Similarly, (Y_{iT1}, Y_{iT2}) are the observed responses corresponding to the i^{th} subject in the test treatment group, $i = 1, 2, \dots, n_T$. Furthermore, assume that (Y_{iC1}, Y_{iC2}) follows a bivariate ZIP model with parameters $\lambda_c, \lambda_{0c}, p_{0c}, p_{1c}$, and p_{2c} for the control treatment, and (Y_{iT1}, Y_{iT2}) follows a bivariate ZIP model with parameters $\lambda_T, \lambda_{0T}, p_{0T}, p_{1T}$, and p_{2T} for the test treatment.

To facilitate the comparison of the two treatments, consider the following transformation of parameters.

$$\begin{aligned}\theta_1 &= \lambda_{0T} - \lambda_{0C} \text{ and } \theta_6 = \lambda_{0C} \Rightarrow \lambda_{0T} = \theta_1 + \theta_6 \\ \theta_2 &= \lambda_T - \lambda_C \text{ and } \theta_7 = \lambda_C \Rightarrow \lambda_T = \theta_2 + \theta_7 \\ \theta_3 &= p_{0T} - p_{0C} \text{ and } \theta_8 = p_{0C} \Rightarrow p_{0T} = \theta_3 + \theta_8 \\ \theta_4 &= p_{1T} - p_{1C} \text{ and } \theta_9 = p_{1C} \Rightarrow p_{1T} = \theta_4 + \theta_9 \\ \theta_5 &= p_{2T} - p_{2C} \text{ and } \theta_{10} = p_{2C} \Rightarrow p_{2T} = \theta_5 + \theta_{10}\end{aligned}\quad (3)$$

Given observations (y_{ij1}, y_{ij2}) , $j = T, C$, $i = 1, 2, \dots, n_j$, define the index sets:

$$\begin{aligned}I_{0j} &= \{i : y_{ij1} = 0 \text{ and } y_{ij2} = 0; i = 1, 2, \dots, n_j\} \\ I_{1j} &= \{i : y_{ij1} \neq 0 \text{ and } y_{ij2} = 0; i = 1, 2, \dots, n_j\} \\ I_{2j} &= \{i : y_{ij1} = 0 \text{ and } y_{ij2} \neq 0; i = 1, 2, \dots, n_j\} \\ \text{and } I_{3j} &= \{i : y_{ij1} \neq 0 \text{ and } y_{ij2} \neq 0; i = 1, 2, \dots, n_j\}\end{aligned}\quad (4)$$

For $i \in I_{kj}$, $j = T, C$ and $k = 0, 1, 2, 3$, let P_{ijk} denotes the probability that the observed response is (y_{ij1}, y_{ij2}) . Then, P_{ijk} is given by:

$$\begin{aligned}P_{iC0} &= \theta_8 + (\theta_9 + \theta_{10}) \exp(-\theta_7) + (1 - \theta_8 - \theta_9 - \theta_{10}) \\ &\quad \exp(-(\theta_6 + \theta_7)) \\ P_{iC1} &= \left[\theta_9 \theta_7^{y_{iC1}} \exp(-\theta_7) + (1 - \theta_8 - \theta_9 - \theta_{10}) \theta_6^{y_{iC1}} \right. \\ &\quad \left. \exp(-(\theta_6 + \theta_7)) \right] / y_{iC1}! \\ P_{iC2} &= \left[\theta_{10} \theta_7^{y_{iC2}} \exp(-\theta_7) + (1 - \theta_8 - \theta_9 - \theta_{10}) \theta_6^{y_{iC2}} \right. \\ &\quad \left. \exp(-(\theta_6 + \theta_7)) \right] / y_{iC2}!\end{aligned}$$

$$\begin{aligned}P_{iC3} &= (1 - \theta_8 - \theta_9 - \theta_{10}) \sum_{j=0}^{\min(y_{iC1}, y_{iC2})} \theta_1^{y_{iC1} + y_{iC2} - 2j} \\ &\quad (\theta_7 - \theta_6)^j \frac{\exp(-(\theta_6 + \theta_7))}{(y_{iC1} - j)!(y_{iC2} - j)!j!}\end{aligned}\quad (5)$$

and

$$\begin{aligned}P_{iT0} &= (\theta_3 + \theta_8) + (\theta_4 + \theta_5 + \theta_9 + \theta_{10}) \\ &\quad \exp(-(\theta_2 + \theta_7)) + (1 - u) \exp(-v) \\ P_{iT1} &= \left[(\theta_4 + \theta_9) (\theta_2 + \theta_7)^{y_{iT1}} \exp(-(\theta_2 + \theta_7)) \right. \\ &\quad \left. + (1 - u) (\theta_1 + \theta_6)^{y_{iT1}} \exp(-v) \right] / y_{iT1}! \\ P_{iT2} &= \left[(\theta_5 + \theta_{10}) (\theta_2 + \theta_7)^{y_{iT2}} \exp(-(\theta_2 + \theta_7)) \right. \\ &\quad \left. + (1 - u) (\theta_1 + \theta_6)^{y_{iT2}} \exp(-v) \right] / y_{iT2}! \\ P_{iT3} &= (1 - u) \sum_{j=0}^{\min(y_{iT1}, y_{iT2})} (\theta_1 + \theta_6)^{y_{iT1} + y_{iT2} - 2j} \\ &\quad (\theta_2 + \theta_7 - \theta_1 - \theta_6)^j \frac{\exp(-v)}{(y_{iT1} - j)!(y_{iT2} - j)!j!}\end{aligned}\quad (6)$$

with $u = \theta_3 + \theta_4 + \theta_5 + \theta_8 + \theta_9 + \theta_{10}$ and $v = \theta_1 + \theta_2 + \theta_6 + \theta_7$.

Based on these observed responses, the log-likelihood function $\ln L$ is given by:

$$L = \prod_{k=0}^3 \prod_{j=C, T} \prod_{i \in I_{kj}} P_{ijk} \Rightarrow \ln L = \sum_{k=0}^3 \sum_{j=C, T} \sum_{i \in I_{kj}} \ln P_{ijk}\quad (7)$$

Denote $\theta = (\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{10})$. Then, the MLEs $\hat{\theta} = (\hat{\theta}_1, \hat{\theta}_2, \hat{\theta}_3, \hat{\theta}_4, \hat{\theta}_5, \hat{\theta}_6, \hat{\theta}_7, \hat{\theta}_8, \hat{\theta}_9, \hat{\theta}_{10})$ of θ can be found by solving the likelihood equations $\frac{\partial \ln L}{\partial \theta_i} = 0$;

$i = 1, \dots, 10$, which are derived by taking the first order derivatives of the log-likelihood function given in Eq. 6 with respect to the unknown parameters. Then, the MLEs of the model parameters $\lambda_c, \lambda_{0c}, p_{0c}, p_{1c}$, and p_{2c} for the control and $\lambda_T, \lambda_{0T}, p_{0T}, p_{1T}$, and p_{2T} for the test treatment can be found easily using the invariance principle. Without loss of generality, assume that both the control and test treatments have the same sample size, i.e., $n_C = n_T = n$. Denote the Fisher information matrix by:

$$I(\theta) = E \left[- \frac{\partial^2 \ln L}{\partial \theta \partial \theta^T} \right]\quad (8)$$

Let,

$$I_1(\theta) = \frac{1}{n} I(\theta)\quad (9)$$

then $I_1(\theta)$ is the Fisher information per unit. The inverse of $I(\theta)$ given in Eq. 8 is the asymptotic covariance matrix of the MLE $\hat{\theta}$ of the model parameters θ . Thus, the

corresponding diagonal elements of $I^{-1}(\theta)$ would be the asymptotic variances of the MLE $\hat{\theta}$. Statistical inference of the individual parameters can be drawn based on this information.

LIKELIHOOD RATIO TESTS FOR THE COMPARISON OF TREATMENTS

In many clinical applications, it is common to test whether there is any difference between a control treatment and a test treatment. If the responses are bivariate ZIP distributed, the problem is formulated as the testing of the following hypotheses:

$$H_0 : \lambda_C = \lambda_T, \lambda_{0C} = \lambda_{0T}, p_{0C} = p_{0T}, p_{1C} = p_{1T}, p_{2C} = p_{2T} \text{ versus } H_A : \text{not all are equal} \quad (10)$$

However, using the transformation given in Eq. 3, this is equivalent to test:

$$H_0 : \theta_1 = \theta_2 = \theta_3 = \theta_4 = \theta_5 = 0 \text{ versus } H_A : \text{Some of these } \theta_i \text{ are not equal to 0} \quad (11)$$

Likelihood ratio test method is used to develop test procedure for these hypotheses. Denote $\theta_0 = (0, 0, 0, 0, 0, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{10})$ and $\hat{\theta}_0 = (0, 0, 0, 0, 0, \hat{\theta}_{06}, \hat{\theta}_{07}, \hat{\theta}_{08}, \hat{\theta}_{09}, \hat{\theta}_{010})$, where $\hat{\theta}_{0i}, i = 6, \dots, 10$ are the MLE of $\theta_i, i = 6, \dots, 10$ under H_0 .

Partition the matrix $i(\theta)$ given in Eq. 9 into:

$$i(\theta) = \begin{pmatrix} i_{aa}(\theta) & i_{ab}(\theta) \\ i_{ba}(\theta) & i_{bb}(\theta) \end{pmatrix}_{10 \times 10} \quad (12)$$

$$\text{where } i_{aa}(\theta) = -\frac{1}{n} E \left(\frac{\partial^2 \ln L}{\partial \theta_i \partial \theta_j} \right)_{i=1, \dots, 5; j=1, \dots, 5} \quad (13)$$

$$i_{bb}(\theta) = -\frac{1}{n} E \left(\frac{\partial^2 \ln L}{\partial \theta_i \partial \theta_j} \right)_{i=6, \dots, 10; j=6, \dots, 10} \quad (14)$$

$$\text{and } i_{ab}(\theta) = -\frac{1}{n} E \left(\frac{\partial^2 \ln L}{\partial \theta_i \partial \theta_j} \right)_{i=1, \dots, 5; j=6, \dots, 10} \quad (15)$$

Based on the results of Cox and Hinkley,^[20] the likelihood ratio test statistic for the hypotheses given in Eq. 11 is:

$$W = 2 \left[\ln L(\hat{\theta}) - \ln L(\hat{\theta}_0) \right] \quad (16)$$

It is easy to verify that the regularity conditions stated in the study by Lehman and Casella^[21] are satisfied. Based on Wilks Theorem, the likelihood ratio statistic W asymptotically follows a central χ^2_5 under the null hypothesis H_0 and a

non-central chi-squared distribution with a non-centrality parameter δ under the alternative hypothesis H_A , where:

$$\delta^2 = n(\theta_1, \theta_2, \theta_3, \theta_4, \theta_5) \begin{bmatrix} i_{aa}(\theta) - i_{ab}(\theta) i_{bb}^{-1}(\theta) i_{ba}(\theta) \end{bmatrix} \begin{pmatrix} \theta_1, \theta_2, \theta_3, \theta_4, \theta_5 \end{pmatrix}^T \quad (17)$$

Thus, the null hypothesis H_0 is rejected at a significance level α if $W > \chi^2_5(\alpha)$, where $\chi^2_5(\alpha)$ is the upper α -quantile of a χ^2_5 distribution. Based on this result, for a given level α , the critical region is given by:

$$\left\{ (y_{ij1}, y_{ij2}), i = 1, 2, \dots, n_j; j = T, C, \mid W > \chi^2_5(\alpha) \right\} \quad (18)$$

and the power function of the test is given by:

$$1 - \beta = P \left\{ W > \chi^2_5(\alpha) \mid H_A \right\} \quad (19)$$

DETERMINATION OF SAMPLE SIZE

In clinical study, it is of interest to determine the required sample size such that the corresponding sample size can achieve a desired power $(1 - \beta)$ for detecting a clinically meaningful difference of the parameters at a prespecified level of significance α . Thus, based on the power function given in Eq. 19, the required sample size n can be determined in such a way that the resulting sample would achieve a given power $(1 - \beta)$. Using normal approximation to the probability given in Eq. 19 (details can be found in Johnson, Kotz and Kemp^[22]):

$$(2 + \delta^2)^{\frac{1}{2}} \left[\left(\frac{W - 1/3}{2 + \delta^2} \right)^{\frac{1}{2}} - \left(1 - \frac{1}{3(2 + \delta^2)} \right)^{\frac{1}{2}} \right] \quad (20)$$

or equivalently,

$$\left(W - \frac{1}{3} \right)^{\frac{1}{2}} - \left(\frac{5 + 3\delta^2}{3} \right)^{\frac{1}{2}} \quad (21)$$

approximately follows a standard normal distribution. Therefore, based on Eq. 19,

$$\left(\chi^2_5(\alpha) - \frac{1}{3} \right)^{\frac{1}{2}} - \left(\frac{5 + 3\delta^2}{3} \right)^{\frac{1}{2}} = -z(\beta) \quad (22)$$

where $z(\beta)$ is the upper β -quantile of a standard normal distribution. Simplification of Eq. 22 gives a formula of the sample size for achieving a $(1 - \beta)$ power as follows:

$$n \geq C^{-1} \left\{ \left[\left(\chi^2_5(\alpha) - \frac{1}{3} \right)^{\frac{1}{2}} + z(\beta) \right]^2 - \frac{5}{3} \right\} \quad (23)$$

where $C = (\theta_1, \theta_2, \theta_3, \theta_4, \theta_5) [i_{aa}(\theta) - i_{ab}(\theta)i_{bb}^{-1}(\theta)i_{ba}(\theta)] (\theta_1, \theta_2, \theta_3, \theta_4, \theta_5)^T$.

For illustration purpose, Yuen, Chow, and Tse^[19] listed the required sample size n for selected combinations of parameter values using $\alpha = 0.05$ and $1 - \beta = 0.8$. In general, their results suggest that the difference of λ_C and λ_T plays an important role in determining the required sample size to discriminate the two bivariate ZIP models. When λ_C and λ_T are close, it requires a very large sample size to achieve the nominal power level.

Since the results presented in Eq. 23 are based on approximation, Yuen, Chow, and Tse^[19] conducted a simulation study to assess the accuracy of these results. Their study showed that the simulated powers are higher than the nominal power level for cases with sample sizes larger than 20. Thus, the required sample sizes derived by the approximation results would give the desired power level, albeit in a somewhat conservative manner. For cases with sample sizes less than 20, the simulated power is lower than the nominal value. There are two possible causes leading to this pattern. One plausible explanation is that the derived sample sizes may be too small to support the estimation of the relatively large number of parameters in the model since there are 10 unknown parameters in the model. On the other hand, it may also due to the fact that the asymptotic approximation results only work for cases with relatively large sample size, say, at least 20.

AN EXAMPLE

A clinical trial for evaluation of a test treatment for patients with addictive drug or substance abuse to illustrate the application of the proposed statistical test described in the previous section. Addiction is a chronic, often relapsing brain disease that causes compulsive drug seeking and use, despite harmful consequences to the addicted individuals and those around him or her. Drug or substance

abuse and addiction have negative consequences for individuals and for society such as family disintegration, loss of employment, failure in school, domestic violence, and child abuse.

In this clinical study, 156 qualified subjects were randomly assigned to receive a test treatment and another 139 subjects were assigned to receive an active control treatment in conjunction with behavioral therapy. The treatment duration was for six months. Clinical assessment such as measurements for social behavior and safety implications of drug abuse and addiction was done at 3 months and 6 months (end point visit). In addition, individual patient diary was used to capture the number of days of illicit drug use at the third month and the sixth month. At the end of the study, of the 156 subjects under the test treatment, 51 of them are with zero values (0, 0); on the other hand, 45 of the 139 control subjects are with (0, 0) values. The corresponding data are listed in Table 1.

In particular, the bivariate ZIP model defined in the section "A Bivariate ZIP Model" is used to model these bivariate data and the likelihood ratio test developed in the section "Likelihood Ratio Tests for the Comparison of Treatments" is used to assess whether there is any difference in the therapeutic effect between the two treatments, namely, control and test treatments. Thus, the assessment is done by comparing the two bivariate ZIP models. In particular, following the model formulation outlined in section III, the hypotheses of interests are:

$$H_0: \lambda_C = \lambda_T, \lambda_{0C} = \lambda_{0T}, P_{0C} = P_{0T}, P_{1C} = P_{1T}, P_{2C} = P_{2T} \text{ versus } H_A: \text{not all are equal} \quad (24)$$

which is equivalent to:

$$H_0: \theta_1 = \theta_2 = \theta_3 = \theta_4 = \theta_5 = 0 \text{ versus } H_A: \text{Some of these } \theta_i \text{ are not equal to 0} \quad (25)$$

Based on the data, the unrestricted MLEs of the parameters are $\hat{\theta} = (-0.666, -0.777, 0.001, -0.105, -0.001, 3.034,$

Table 1 Data used in the example

(4, 2)	(4, 3)	(4, 3)	(4, 4)	(4, 6)	(4, 7)	(4, 8)	(4, 9)	(5, 1)	(5, 1)
(5, 2)	(5, 3)	(5, 4)	(5, 5)	(6, 0)	(6, 4)	(6, 6)	(6, 14)	(8, 0)	(8, 0)
(8, 2)	(8, 5)	(8, 8)	(8, 11)	(9, 4)	(9, 8)	(10, 0)	(10, 5)	(10, 8)	(11, 1)
(11, 8)	(11, 9)	(11, 13)	(13, 10)	(13, 13)					

4.6737, 0.320, 0.212, 0.137). Consequently, the MLEs and the corresponding standard errors (listed inside the brackets) of the model parameters are summarized in the following:

	λ_0	λ	p_0	p_1	p_2
Control	3.034 (0.143)	4.673 (0.111)	0.320 (0.002)	0.212 (0.002)	0.137 (0.002)
Treatment	2.368 (0.067)	3.896 (0.036)	0.321 (0.001)	0.107 (0.001)	0.136 (0.001)

Under H_0 , the MLEs are $\hat{\theta}_0 = (0, 0, 0, 0, 0, 2.623, 4.246, 0.321, 0.157, 0.136)$.

Furthermore, the test statistic $W = 2 \times [-1232.51 - (-1239.77)] = 14.53$, which is larger than $\chi^2_5(0.05) = 11.07$. Therefore, we reject H_0 at a 5% level of significance. The results indicate that there is a significant difference in therapy effect between the test treatment and the control treatment.

CONCLUSION

This entry discusses the problem of testing treatment difference in the occurrence of a study end point in a randomized parallel-group comparative clinical trial with repeated responses. These occurrence counts usually could include a large proportion of zeros and are usually modeled by a ZIP model to give an accurate assessment of the treatment effect. However, there is a need to extend a univariate ZIP model to the multivariate case, since repeated responses are observed in the study. The works in this entry demonstrate that a bivariate ZIP model can be used to compare the effect of two treatments in a two-armed clinical trial. In particular, likelihood ratio test is derived to test the homogeneity of the two bivariate ZIP populations. An approximate formula to determine the

required sample sizes to achieve a desired power is given. Although the discussion of the example and the results given are based on only two repeated responses, it can be shown that the model can be readily extended to more than two repeated responses. However, the number of parameters would inevitably increase, which would require a relatively large data set and impose considerable amount of difficulty on the estimation of the model parameters. In any event, the proposed model provides a viable tool for practitioners to assess whether a new treatment is more effective than another treatment when the responses are repeated counts with usually large proportion of zeros.

Blinded Sample Size Re-Estimation

Chien-Hua Wu

Department of Applied Mathematics, Chung-Yuan Christian University, Chung-Li, Taiwan

Abstract

The sample size calculation plays an important role in clinical trials. Estimation of sample size in clinical trials requires knowledge of parameters. When there is uncertainty about some of the parameters, it can be challenging to determine the number of subjects required for the study. This article provides a method via the transition probability matrix to re-estimate the sample size based on interim data while the blind procedure is preserved. The examples of categorical response, continuous response and survival data are provided to illustrate the use of proposed methods.

Keywords: Sample Size; Transition Probability Matrix; Continuous Response; Categorical Response; Survival Analysis.

INTRODUCTION

All human subject researches, particularly in large confirmatory Phase III trials, must provide the evidence on the efficacy and safety of medical interventions for filing new drug application submission. The clinical trial protocol blueprints the protection of safeties, rights and welfare of the human subjects, and promises the quality of data collection. Interim analyses play an integral role in clinical trials for the possibility of stopping the trial early for safety concerns, and/or futility, and/or early evidence of efficacy. The 1998 International Conference on Harmonization guidance for industry “E9 Statistical Principles for Clinical Trials”^[1] states that all staff involved in the conduct of the trial should remain blind to the results of analyses, because of the possibility that their attitudes to the trial will be modified and cause changes in the characteristics of patients to be recruited or biases in treatment comparisons. To ensure the confidentiality of interim analysis, the techniques of sample size re-estimation without breaking the blind are proposed by Gould and Shih^[2] using EM algorithm for continuous responses and Shih and Zhao^[3] stratifying the randomization procedure for binary outcomes. Bristol and Shurzinske^[4] propose a method to estimate the variance. Kieser and Friede^[5] provide the procedures for blinded sample size adjustment that do not affect the type I error rate. Xing and Ganju^[6] uses the randomization block to estimate the variance without breaking the blind. Ganju and Xing^[7] extend previous work to estimate the within-group variance of a continuous endpoint. Masking the treatment effect, Shih^[8] perturbs unblinding to estimate the variance. Friede and Kieser^[9] compare the blinded sample size re-estimation procedures with respect to bias and variance of the variance estimators. Using the

dummy strata, Wu^[10] extends the work of Shih and Zhao^[3] to continuous endpoints. Additionally, Wu^[11] suggests the sponsor may stop the trial early because efficacy is unequivocally established in a crossover design. Without loss integrity of clinical trials, the randomization blocks with the primary outcomes are used to estimate the sample size in the middle of clinical trial masking the randomization codes in the released data.

CATEGORICAL RESPONSE

Suppose we have a discrete variable y taking p categories and another variable having b treatment groups in the original data, and a discrete variable x taking p categories and a variable with a randomization blocks in the released data. The responses are relocated from the treatment groups of the original data to the randomization blocks of the released data via the transition probability matrix. Let $\mathbf{y}_j = (y_{j1}, \dots, y_{jp})'$ be the random vector at the j th group satisfied $y_{ik} = 1$ or 0 and $\sum_{k=1}^p y_{jk} = 1$ in the original data, where $j = 1, 2, \dots, b$. Let $\mathbf{x}_i = (x_{i1}, \dots, x_{ip})'$ be the random vector at the i th block satisfied $x_{ik} = 1$ or 0 and $\sum_{k=1}^p x_{ik} = 1$ in the released data, where $i = 1, 2, \dots, a$. For k th category, a transition probability matrix Θ is defined as a matrix composed of elements θ_{ij} such that the probability

$$\begin{aligned}\pi_{x_{ik}} &= E(x_{ik}) = P(x_{ik} = 1) \\ &= \sum_{j=1}^b P(x_{ik} = 1 | y_{jk} = 1) P(y_{jk} = 1) \\ &= \sum_{j=1}^b \theta_{ij} \pi_{y_{jk}}\end{aligned}$$

where $\theta_{ij} = P(x_{ik} = 1 | y_{jk} = 1)$ and $\pi_{yjk} = P(y_{jk} = 1)$. For simplicity,

$$\begin{pmatrix} \pi_{x_{1k}} \\ \pi_{x_{2k}} \\ \vdots \\ \pi_{x_{ak}} \end{pmatrix} = \begin{pmatrix} \theta_{11} & \theta_{12} & \cdots & \theta_{1b} \\ \theta_{21} & \theta_{22} & \cdots & \theta_{2b} \\ \vdots & \vdots & \ddots & \vdots \\ \theta_{a1} & \theta_{a2} & \cdots & \theta_{ab} \end{pmatrix} \begin{pmatrix} \pi_{y_{1k}} \\ \pi_{y_{2k}} \\ \vdots \\ \pi_{y_{bk}} \end{pmatrix} \quad (1)$$

where $k = 1, 2, \dots, p$. Note that $\sum_{k=1}^p \pi_{x_{ik}} = 1$, $\sum_{k=1}^p \pi_{y_{jk}} = 1$, and $\sum_{j=1}^b \theta_{ij} = 1$.

Letting $\pi_x = (\pi_{x_{i1}}, \pi_{x_{i2}}, \dots, \pi_{x_{ip}})'$ and $\pi_y = (\pi_{y_{j1}}, \pi_{y_{j2}}, \dots, \pi_{y_{jp}})'$, Eq. (1) becomes

$$\begin{pmatrix} \pi_{x_1} \\ \pi_{x_2} \\ \vdots \\ \pi_{x_a} \end{pmatrix} = \begin{pmatrix} \theta_{11} I_p & \theta_{12} I_p & \cdots & \theta_{1b} I_p \\ \theta_{21} I_p & \theta_{22} I_p & \cdots & \theta_{2b} I_p \\ \vdots & \vdots & \ddots & \vdots \\ \theta_{a1} I_p & \theta_{a2} I_p & \cdots & \theta_{ab} I_p \end{pmatrix} \begin{pmatrix} \pi_{y_1} \\ \pi_{y_2} \\ \vdots \\ \pi_{y_b} \end{pmatrix}$$

$$= \begin{pmatrix} \theta_{11} & \theta_{12} & \cdots & \theta_{1b} \\ \theta_{21} & \theta_{22} & \cdots & \theta_{2b} \\ \vdots & \vdots & \ddots & \vdots \\ \theta_{a1} & \theta_{a2} & \cdots & \theta_{ab} \end{pmatrix} \otimes I_p \begin{pmatrix} \pi_{y_1} \\ \pi_{y_2} \\ \vdots \\ \pi_{y_b} \end{pmatrix}$$

$$= \Theta \otimes I_p \begin{pmatrix} \pi_{y_1} \\ \pi_{y_2} \\ \vdots \\ \pi_{y_b} \end{pmatrix} \quad (2)$$

or $\pi_x = (\Theta \otimes I_p) \pi_y$, where I_p denotes the identity matrix of size p . If $a = b$ and $\Theta \otimes I_p$ is a nonsingular matrix, we have

$$\begin{aligned} \pi_y &= (\Theta \otimes I_p)^{-1} \pi_x \\ &= (\Theta^{-1} \otimes I_p^{-1}) \pi_x \\ &= (\Theta^{-1} \otimes I_p) \pi_x. \end{aligned} \quad (3)$$

If $a = b = p = 2$, the estimator for Eq. (3) is the same as the estimator provided by Shih and Zhao^[3]. The unbiased estimators of π_{y11} and π_{y21} are given by

$$\begin{pmatrix} \hat{\pi}_{y11} \\ \hat{\pi}_{y21} \end{pmatrix} = \begin{pmatrix} \theta_{11} & \theta_{12} \\ \theta_{21} & \theta_{22} \end{pmatrix}^{-1} \begin{pmatrix} \hat{\pi}_{x11} \\ \hat{\pi}_{x21} \end{pmatrix}.$$

Letting $\theta_{11} = \theta_{22} = \theta$, this becomes

$$\begin{pmatrix} \hat{\pi}_{y11} \\ \hat{\pi}_{y21} \end{pmatrix} = \begin{pmatrix} \theta & 1-\theta \\ 1-\theta & \theta \end{pmatrix}^{-1} \begin{pmatrix} \hat{\pi}_{x11} \\ \hat{\pi}_{x21} \end{pmatrix}$$

$$= \frac{1}{2\theta-1} \begin{pmatrix} \theta & -(1-\theta) \\ -(1-\theta) & \theta \end{pmatrix} \begin{pmatrix} \hat{\pi}_{x11} \\ \hat{\pi}_{x21} \end{pmatrix}.$$

If we have n_i observations in i th block, by the Central Limit Theorem, this implies

$$\hat{\pi}_{x_{i1}} - \pi_{x_{i1}} \xrightarrow{D} N\left(0, \pi_{x_{i1}}(1-\pi_{x_{i1}})/n_i\right).$$

for $i = 1, 2$. By the delta method, we have

$$\hat{\pi}_{y11} - \pi_{y11} \xrightarrow{D} N\left(0, V(\hat{\pi}_{y11})\right)$$

and

$$\hat{\pi}_{y21} - \pi_{y21} \xrightarrow{D} N\left(0, V(\hat{\pi}_{y21})\right)$$

where $V(\hat{\pi}_{y11}) = \frac{1}{(2\theta-1)^2} \left(\theta^2 \frac{\pi_{x11}(1-\pi_{x11})}{n_1} + (1-\theta)^2 \frac{\pi_{x21}(1-\pi_{x21})}{n_2} \right)$

and

$$V(\hat{\pi}_{y21}) = \frac{1}{(2\theta-1)^2} \left((1-\theta)^2 \frac{\pi_{x11}(1-\pi_{x11})}{n_1} + \theta^2 \frac{\pi_{x21}(1-\pi_{x21})}{n_2} \right).$$

Thus,

$$(\hat{\pi}_{y11} - \hat{\pi}_{y21}) - (\pi_{y11} - \pi_{y21}) \xrightarrow{D} N\left(0, V(\hat{\pi}_{y11}) + V(\hat{\pi}_{y21})\right).$$

To test whether there is a difference between the mean response rates of the test drug and the reference drug, the following hypotheses are usually considered:

$$H_0 : \pi_{y11} = \pi_{y21} \text{ versus } H_a : \pi_{y11} \neq \pi_{y21}.$$

We reject the null hypothesis at the α level of significance if

$$\left| \frac{\hat{\pi}_{y11} - \hat{\pi}_{y21}}{\sqrt{V(\hat{\pi}_{y11}) + V(\hat{\pi}_{y21})}} \right| > z_{\alpha/2}$$

Under the alternative hypothesis $H_a : \pi_{y11} \neq \pi_{y21}$, the power of the above test is approximately

$$\Phi \left(\frac{\pi_{y11} - \pi_{y21}}{\sqrt{V(\hat{\pi}_{y11}) + V(\hat{\pi}_{y21})}} - z_{\alpha/2} \right).$$

As a result, the sample size needed for achieving a power of $1 - \beta$ can be obtained by the following equation:

$$\frac{\pi_{y11} - \pi_{y21}}{\sqrt{V(\hat{\pi}_{y11}) + V(\hat{\pi}_{y21})}} - z_{\alpha/2} = z_{\beta}.$$

After some algebra, this leads to

$$\begin{aligned} & \frac{(2\theta - 1)^2 \left(\frac{\pi_{y11} - \pi_{y21}}{z_{\beta} + z_{\alpha/2}} \right)^2}{\theta^2 + (1 - \theta)^2} \\ &= \frac{\pi_{x11}(1 - \pi_{x11})}{n_1} + \frac{\pi_{x21}(1 - \pi_{x21})}{n_2}. \end{aligned}$$

If $n = n_1 = n_2$, then the blind sample size is given by

$$\begin{aligned} n &= \left(\pi_{x11}(1 - \pi_{x11}) + \pi_{x21}(1 - \pi_{x21}) \right) \\ &\times \frac{\theta^2 + (1 - \theta)^2}{(2\theta - 1)^2} \left(\frac{z_{\beta} + z_{\alpha/2}}{\pi_{y11} - \pi_{y21}} \right)^2. \end{aligned} \quad (4)$$

Comparing to the unblind sample size^[12]

$$m = \left(\pi_{y11}(1 - \pi_{y11}) + \pi_{y21}(1 - \pi_{y21}) \right) \left(\frac{Z_{\beta} + Z_{\alpha/2}}{\pi_{y11} - \pi_{y21}} \right)^2,$$

we need extra information in order to estimate the blind sample size. That is, the information of θ , π_{x11} , and π_{x21} . If $\theta = 1$, $\pi_{y11} = \pi_{x11}$ and $\pi_{y21} = \pi_{x21}$, then $n = m$. In fact, the blind sample size is greater than or equal to the unblind sample size in the balance design, which is shown in the following theorem.

Theorem 1 $n \geq m$.

Proof 1 Since $\pi_{x11} = \theta\pi_{y11} + (1 - \theta)\pi_{y21}$ and $\pi_{x21} = (1 - \theta)\pi_{y11} + \theta\pi_{y21}$, the blind sample of Eq. (4) can be expressed as

$$\begin{aligned} n &= \left(\pi_{x11}(1 - \pi_{x11}) + \pi_{x21}(1 - \pi_{x21}) \right) \\ &\times \frac{\theta^2 + (1 - \theta)^2}{(2\theta - 1)^2} \left(\frac{Z_{\beta} + Z_{\alpha/2}}{\pi_{y11} - \pi_{y21}} \right)^2 \\ &= \left(\pi_{y11}(1 - \pi_{y11}) + \pi_{y21}(1 - \pi_{y21}) \right) \\ &\times \frac{\theta^2 + (1 - \theta)^2}{(2\theta - 1)^2} \left(\frac{Z_{\beta} + Z_{\alpha/2}}{\pi_{y11} - \pi_{y21}} \right)^2 \\ &= \left(\pi_{y11}(1 - \pi_{y11}) + \pi_{y21}(1 - \pi_{y21}) \right) \\ &\times \frac{1}{2} \left(1 + \frac{1}{(2\theta - 1)^2} \right) \left(\frac{Z_{\beta} + Z_{\alpha/2}}{\pi_{y11} - \pi_{y21}} \right)^2 \\ &\geq \left(\pi_{y11}(1 - \pi_{y11}) + \pi_{y21}(1 - \pi_{y21}) \right) \left(\frac{Z_{\beta} + Z_{\alpha/2}}{\pi_{y11} - \pi_{y21}} \right)^2 \\ &= m \end{aligned} \quad (5)$$

due to the fact that $\frac{1}{(2\theta - 1)^2} \geq 1$.

Corollary 1 The blind sample size is getting close to the unblind sample size as θ approaches to either 0 or 1.

Proof 2 The result is concluded in Eq. (5).

Non-inferiority or Superiority Trials

Suppose an investigator plans to demonstrate the study drug is superior (or non-inferior) to the competitor. The null hypothesis states that the new treatment is not superior (or inferior) to the active control at certain level of margin, say δ . The alternative hypothesis states that the study drug is superior (non-inferior) to the competitor. It can be written in terms of mathematical formulae such as

$$H_0 : \pi_{y11} - \pi_{y21} \leq \delta \quad \text{versus} \quad H_a : \pi_{y11} - \pi_{y21} > \delta$$

where δ is the superiority or non-inferiority margin. The margin $\delta > 0$ can be used to show that the new treatment is superior by a fixed amount δ . Setting the margin $\delta < 0$, we claim that the active treatment is less effective than the control treatment by no more than δ if the null hypothesis is rejected. We reject the null hypothesis at the α level of significance if

$$\left| \frac{\hat{\pi}_{y11} - \hat{\pi}_{y21} - \delta}{\sqrt{V(\hat{\pi}_{y11}) + V(\hat{\pi}_{y21})}} \right| > Z_{\alpha}$$

Under the alternative hypothesis $H_a : \pi_{y11} - \pi_{y21} > \delta$, the power of the above test is approximately

$$\Phi \left(\frac{\pi_{y11} - \pi_{y21} - \delta}{\sqrt{V(\hat{\pi}_{y11}) + V(\hat{\pi}_{y21})}} - Z_{\alpha} \right).$$

As a result, the sample size needed for achieving a power of $1 - \beta$ can be obtained by the following equation:

$$\frac{\pi_{y11} - \pi_{y21} - \delta}{\sqrt{V(\hat{\pi}_{y11}) + V(\hat{\pi}_{y21})}} - Z_{\alpha} = Z_{\beta}.$$

After some algebra, this leads to

$$\begin{aligned} & \frac{(2\theta - 1)^2 \left(\frac{\pi_{y11} - \pi_{y21} - \delta}{Z_{\beta} + Z_{\alpha}} \right)^2}{\theta^2 + (1 - \theta)^2} \\ &= \frac{\pi_{x11}(1 - \pi_{x11})}{n_1} + \frac{\pi_{x21}(1 - \pi_{x21})}{n_2} \end{aligned}$$

If $n = n_1 = n_2$, then the blind sample size is given by

$$\begin{aligned} n &= \left(\pi_{x11}(1 - \pi_{x11}) + \pi_{x21}(1 - \pi_{x21}) \right) \\ &\times \frac{\theta^2 + (1 - \theta)^2}{(2\theta - 1)^2} \left(\frac{Z_{\beta} + Z_{\alpha}}{\pi_{y11} - \pi_{y21} - \delta} \right)^2. \end{aligned} \quad (6)$$

Equivalence Trials

The objective of this section is to demonstrate that two treatments have no clinically meaningful difference. The

null hypothesis and alternative hypothesis can be written in the following form

$$H_0: |\pi_{y11} - \pi_{y21}| \geq \delta \quad \text{versus} \quad H_a: |\pi_{y11} - \pi_{y21}| < \delta$$

where δ is the equivalent margin. The equivalence test are performed using two one-sided tests. We reject the null hypothesis at the α level of significance if

$$\frac{\hat{\pi}_{y11} - \hat{\pi}_{y21} - \delta}{\sqrt{V(\hat{\pi}_{y11}) + V(\hat{\pi}_{y21})}} < -Z_\alpha$$

and

$$\frac{\hat{\pi}_{y11} - \hat{\pi}_{y21} - \delta}{\sqrt{V(\hat{\pi}_{y11}) + V(\hat{\pi}_{y21})}} < -Z_\alpha$$

Under the alternative hypothesis $H_a: |\pi_{y11} - \pi_{y21}| < \delta$, the power of the above test is approximately

$$2\Phi\left(\frac{\delta - |\pi_{y11} - \pi_{y21}|}{\sqrt{V(\hat{\pi}_{y11}) + V(\hat{\pi}_{y21})}} - Z_\alpha\right) - 1.$$

As a result, the sample size needed for achieving a power of $1 - \beta$ can be obtained by the following equation:

$$\frac{\delta - |\pi_{y11} - \pi_{y21}|}{\sqrt{V(\hat{\pi}_{y11}) + V(\hat{\pi}_{y21})}} - Z_\alpha = Z_{\beta/2}.$$

After some algebra, this leads to

$$\begin{aligned} & \frac{(2\theta - 1)^2}{\theta^2 + (1 - \theta)^2} \left(\frac{\delta - |\pi_{y11} - \pi_{y21}|}{Z_{\beta/2} + Z_\alpha} \right)^2 \\ &= \frac{\pi_{x11}(1 - \pi_{x11})}{n_1} + \frac{\pi_{x21}(1 - \pi_{x21})}{n_2} \end{aligned}$$

If $n = n_1 = n_2$, then the blind sample size is given by

$$\begin{aligned} n &= \left(\pi_{x11}(1 - \pi_{x11}) + \pi_{x21}(1 - \pi_{x21}) \right) \\ &\times \frac{\theta^2 + (1 - \theta)^2}{(2\theta - 1)^2} \left(\frac{Z_{\beta/2} + Z_\alpha}{\delta - |\pi_{y11} - \pi_{y21}|} \right)^2. \end{aligned}$$

Example

McIntyre et al. (2005)^[16] conducted a multicenter, randomized controlled trial to compare buccal midazolam with rectal diazepam for emergency-room treatment of children aged 6 months and older presenting to hospital with active seizures and without intravenous access. The results have shown that therapeutic success was 56% for buccal midazolam and 27% for rectal diazepam. Suppose now we wish to design a new study to

investigate a new treatment with buccal midazolam as the control. We expect this new treatment to increase the chances of success to 66%. The sponsor has confident about the incidence rate of 56% in the control group, but they are not sure about the 66% incidence rate in the test group. Thus, an interim analysis masking the randomization codes is planned to allow for sample size re-estimation based on observed block difference. Here, the sample proportions for each randomization block are $\hat{\pi}_{x11} = 0.59$ and $\hat{\pi}_{x11} = 0.64$. We wish to have 80% power and a two-sided significance level of 5%. Assuming the superiority margin is 0.05. Considering the transition probability $\theta = 0.8$, the estimated blind sample size of Eq. (6) is evaluated by

$$\begin{aligned} \hat{n} &= \left(\pi_{x11}(1 - \pi_{x11}) + \pi_{x21}(1 - \pi_{x21}) \right) \\ &\frac{\theta^2 + (1 - \theta)^2}{(2\theta - 1)^2} \left(\frac{Z_\beta + Z_\alpha}{\pi_{y11} - \pi_{y21} - \delta} \right)^2 \\ &= (0.59(1 - 0.59) + 0.64(1 - 0.64)) \\ &\frac{0.8 + (1 - 0.8)^2}{(2 \times 0.8 - 1)^2} \left(\frac{0.84 + 1.64}{0.66 - 0.56 - 0.05} \right)^2 \\ &= 2207 \text{ subjects for each block.} \end{aligned}$$

CONTINUOUS RESPONSE

Suppose we have a randomization blocks and b treatment groups. Let y_j denote the original response in the j th group for $j = 1, 2, \dots, b$. Let $x_i = \sum_{j=1}^b I_{ij} y_j$ be the relocated response from one of the treatment groups to the i th block, where

$$I_{ij} = \begin{cases} 1, & \text{if the subject relocates} \\ & \text{the } j\text{th group to the } i\text{th blocks,} \\ 0, & \text{otherwise.} \end{cases}$$

Note that $\sum_{j=1}^b I_{ij} = 1$ for $i = 1, 2, \dots, a$. Collecting all of x 's, y 's and I 's, this can expressed in a linear model. That is,

$$\begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_a \end{pmatrix} = \begin{pmatrix} I_{11} & I_{12} & \cdots & I_{1b} \\ I_{21} & I_{22} & \cdots & I_{2b} \\ \vdots & \vdots & \vdots & \vdots \\ I_{a1} & I_{a2} & \cdots & I_{ab} \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \\ \vdots \\ y_b \end{pmatrix} \quad (7)$$

or $\mathbf{x} = \mathbf{I}\mathbf{y}$. Taking the expectation of both sides of Eq. (7), we have

$$\boldsymbol{\mu}_x = E(\mathbf{x}) = E(\mathbf{I}\mathbf{y}) = E(\mathbf{I})E(\mathbf{y}) = \Theta\boldsymbol{\mu}_y \quad (8)$$

if $\mathbf{I}$ and $\mathbf{y}$ are independent. The transition probability matrix is given by

$$\Theta = \begin{pmatrix} \theta_{11} & \theta_{12} & \cdots & \theta_{1b} \\ \theta_{21} & \theta_{22} & \cdots & \theta_{2b} \\ \vdots & \vdots & \vdots & \vdots \\ \theta_{a1} & \theta_{a2} & \cdots & \theta_{ab} \end{pmatrix} \quad (9)$$

where the random vector $\mathbf{I}_i = (I_{i1}, I_{i12}, \dots, I_{ib})'$ has the probability vector $\boldsymbol{\theta}_i = (\theta_{i1}, \theta_{i12}, \dots, \theta_{ib})'$ and $\sum_{j=1}^b \theta_{ij} = 1$ for all i . If $a = b$ and the transition probability matrix Θ is nonsingular, the mean vector of treatment responses in Eq. (8) becomes

$$\boldsymbol{\mu}_y = \Theta^{-1} \boldsymbol{\mu}_x. \quad (10)$$

The vector estimator $\hat{\boldsymbol{\mu}}_y$ of (10) is unbiased if we have unbiased estimator $\hat{\boldsymbol{\mu}}_x$. Considering $a = b = 2$ and setting $\theta_{11} = \theta_{22} = \theta$, Eq. (10) becomes

$$\begin{pmatrix} \mu_{y1} \\ \mu_{y2} \end{pmatrix} = \begin{pmatrix} \theta & 1-\theta \\ 1-\theta & \theta \end{pmatrix}^{-1} \begin{pmatrix} \mu_{x1} \\ \mu_{x2} \end{pmatrix} \\ = \frac{1}{2\theta-1} \begin{pmatrix} \theta & -(1-\theta) \\ -(1-\theta) & \theta \end{pmatrix} \begin{pmatrix} \mu_{x1} \\ \mu_{x2} \end{pmatrix}.$$

Let x_{ik} be the response observed from the k th subject in the i th block, where $k = 1, \dots, n$ and $i = 1, 2$. The unbiased estimators of μ_{x1} and μ_{x2} are $\hat{\mu}_{x1} = \bar{x}_1$ and $\hat{\mu}_{x2} = \bar{x}_2$, respectively. If x_{ik} 's are normally distributed and independent with mean μ_{xi} and common variance σ_x^2 , then the estimators

$$\hat{\mu}_{y1} = \frac{1}{2\theta-1} (\theta \hat{\mu}_{x1} + (1-\theta) \hat{\mu}_{x2})$$

and

$$\hat{\mu}_{y2} = \frac{1}{2\theta-1} ((1-\theta) \hat{\mu}_{x1} + \theta \hat{\mu}_{x2})$$

are also normally distributed with mean μ_{y1} and μ_{y2} , respectively, and common variance $\frac{1}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n$. This follows that

$$\hat{\mu}_{y1} - \hat{\mu}_{y2} \sim N \left(\mu_{y1} - \mu_{y2}, \frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n \right).$$

Note that in the balanced design the population treatment variance

$$\sigma_y^2 = \frac{1}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 \quad (11)$$

if $\sigma_{y1} = \sigma_{y2} = \sigma_y$. The objective is to test whether there is a difference between the mean responses of the test drug and the placebo control or active control. Hence, the following hypotheses are considered:

$$H_0 : \mu_{y1} = \mu_{y2} \quad \text{versus} \quad H_a : \mu_{y1} \neq \mu_{y2}$$

When σ_x^2 is known, the null hypothesis H_0 is rejected at the significance level α if

$$\left| \frac{\hat{\mu}_{y1} - \hat{\mu}_{y2}}{\sqrt{\frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n}} \right| > Z_{\alpha/2}$$

Under the alternative hypothesis that $H_a : \mu_{y1} \neq \mu_{y2}$, the power of the above test is

$$\begin{aligned} 1 - \beta &= P \left(\left| \frac{\hat{\mu}_{y1} - \hat{\mu}_{y2}}{\sqrt{\frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n}} \right| > Z_{\alpha/2} \right) \\ &= P \left(Z < -Z_{\alpha/2} - \frac{\mu_{y1} - \mu_{y2}}{\sqrt{\frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n}} \right) \\ &\quad + P \left(Z < -Z_{\alpha/2} + \frac{\mu_{y1} - \mu_{y2}}{\sqrt{\frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n}} \right) \\ &= \Phi \left(-Z_{\alpha/2} - \frac{\mu_{y1} - \mu_{y2}}{\sqrt{\frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n}} \right) \\ &\quad + \Phi \left(-Z_{\alpha/2} + \frac{\mu_{y1} - \mu_{y2}}{\sqrt{\frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n}} \right) \end{aligned}$$

if $\mu_{y1} > \mu_{y2}$. Ignoring the term of the right hand side of the equation, i.e.

$$\Phi \left(-Z_{\alpha/2} - \frac{(\mu_{y1} - \mu_{y2})}{\sqrt{\frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n}} \right) \leq \alpha/2, \text{ the power}$$

can be expressed as

$$1 - \beta \approx \Phi \left(-Z_{\alpha/2} + \frac{\mu_{y1} - \mu_{y2}}{\sqrt{\frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n}} \right).$$

Similarly, the power can be approximated by

$$1 - \beta \approx \Phi \left(-Z_{\alpha/2} - \frac{\mu_{y1} - \mu_{y2}}{\sqrt{\frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n}} \right).$$

if $\mu_{y1} < \mu_{y2}$. In summary, we have the following result

$$1 - \beta \approx \Phi \left(-Z_{\alpha/2} + \frac{|\mu_{y1} - \mu_{y2}|}{\sqrt{\frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2 / n}} \right).$$

The sample size needed to achieve power $1 - \beta$ can be obtained by solving the following equation

$$\frac{|\mu_{y1} - \mu_{y2}|}{\sqrt{\frac{2}{(2\theta - 1)^2}(\theta^2 + (1 - \theta)^2)\sigma_x^2/n}} - Z_{\alpha/2} = Z_{\beta}.$$

The blind sample size can be expressed as

$$n = \frac{(Z_{\alpha/2} + Z_{\beta})^2}{(\mu_{y1} - \mu_{y2})^2} \frac{2}{(2\theta - 1)^2} (\theta^2 + (1 - \theta)^2) \sigma_x^2. \quad (12)$$

The population variance of the randomization blocks can be estimated by the pool sample variance in the middle of clinical trial, unaware of which group subjects belong to. That is,

$$\hat{\sigma}_x^2 = \frac{\sum_{i=1}^2 \sum_{k=1}^n (x_{ik} - \hat{x}_i)^2}{2n - 2}.$$

The blind sample size of Eq. (12) is then estimated by

$$\hat{n} = \frac{(z_{\alpha/2} + z_{\beta})^2}{(\mu_{y1} - \mu_{y2})^2} \frac{2}{(2\theta - 1)^2} (\theta^2 + (1 - \theta)^2) \hat{\sigma}_x^2. \quad (13)$$

The probability θ provided in the protocol is the proportion of the first treatment assigned in the first block. Taking the expectations on both side, we have

$$\begin{aligned} E(\hat{n}) &= \frac{(z_{\alpha/2} + z_{\beta})^2}{(\mu_{y1} - \mu_{y2})^2} \frac{2}{(2\theta - 1)^2} (\theta^2 + (1 - \theta)^2) E(\hat{\sigma}_x^2) \\ &= \frac{(z_{\alpha/2} + z_{\beta})^2}{(\mu_{y1} - \mu_{y2})^2} \frac{2}{(2\theta - 1)^2} (\theta^2 + (1 - \theta)^2) \sigma_x^2 \\ &= \frac{2(z_{\alpha/2} + z_{\beta})^2 \sigma_y^2}{(\mu_{y1} - \mu_{y2})^2} \\ &= E(\tilde{n}) \end{aligned}$$

by Eq. (11). Here, the the unblind sample size^[12] is

$$\hat{n} = \frac{2(Z_{\alpha/2} + Z_{\beta})^2 \hat{\sigma}_y^2}{(\mu_{y1} - \mu_{y2})^2}$$

where $\hat{\sigma}_y^2 = \sum_{i=1}^2 \sum_{k'=1}^2 (y_{i'k'} - \bar{y}_{i'})^2 / (2n - 2)$ is an unbiased estimator of σ_y^2 . Its variance is given by

$$V(\tilde{n}) = \left[\frac{2(Z_{\alpha/2} + Z_{\beta})^2}{(\mu_{y1} - \mu_{y2})^2} \right]^2 \frac{2\sigma_y^4}{2n - 2}$$

due to the fact that $V\left(\frac{(2n - 2)\hat{\sigma}_y^2}{\sigma_y^2}\right) = V(\chi^2(2n - 2))$ and $V(\chi^2(2n - 2)) = 2(2n - 2)$.

The variance of $\hat{n}$ Eq. (13) is evaluated by

$$\begin{aligned} V(\tilde{n}) &= \left[\frac{(z_{\alpha/2} + z_{\beta})^2}{(\mu_{y1} - \mu_{y2})^2} \frac{2}{(2\theta - 1)^2} (\theta^2 + (1 - \theta)^2) \right]^2 \\ &\quad \times \frac{2\sigma_x^4}{2n - 2} \\ &= \left[\frac{2(z_{\alpha/2} + z_{\beta})^2}{(\mu_{y1} - \mu_{y2})^2} \right]^2 \frac{1}{(2\theta - 1)^4} (\theta^2 + (1 - \theta)^2)^2 \\ &\quad \times \frac{2\sigma_x^4}{2n - 2} \\ &= \left[\frac{2(z_{\alpha/2} + z_{\beta})^2}{(\mu_{y1} - \mu_{y2})^2} \right]^2 \left(\frac{\theta^2 + (1 - \theta)^2}{(2\theta - 1)^2} \sigma_x^2 \right)^2 \\ &\quad \times \frac{2}{2n - 2} \\ &= \left[\frac{2(z_{\alpha/2} + z_{\beta})^2}{(\mu_{y1} - \mu_{y2})^2} \right]^2 \frac{2\sigma_y^4}{2n - 2} \\ &= V(\hat{n}). \end{aligned}$$

In conclusion, we have an unbiased estimator of blind sample size and its variance is the same as the variance of the unblind sample size.

ANOVA Model

In clinical trial, the number of the randomization blocks is most likely more than the number of treatments (i.e. $a > b$). Thus, the inverse of the transition probability matrix Θ in Eq. (10) is not held. The sample size can be re-evaluated alternatively by using the analysis of variance model if Θ is not a square matrix. Suppose the response x_{ij} for j th subject in the i th block follows a unknown distribution with mean μ_{xi} and variance η^2 for $j = 1, 2, \dots, n_i$. This can be written in a linear form as

$$\begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_a \end{pmatrix} = \begin{pmatrix} \mathbf{1}_{n1} & \mathbf{0}_{n1} & \cdots & \mathbf{0}_{n1} \\ \mathbf{0}_{n2} & \mathbf{1}_{n2} & \cdots & \mathbf{0}_{n2} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0}_{na} & \mathbf{0}_{na} & \cdots & \mathbf{1}_{na} \end{pmatrix} \begin{pmatrix} \mu_{x1} \\ \mu_{x2} \\ \vdots \\ \mu_{xa} \end{pmatrix} + \begin{pmatrix} \epsilon_1 \\ \epsilon_2 \\ \vdots \\ \epsilon_a \end{pmatrix} \quad (14)$$

or simplified as

$$\mathbf{x} = \mathbf{A}\boldsymbol{\mu}_x + \boldsymbol{\epsilon}$$

where $\boldsymbol{\epsilon}_i = (\epsilon_{i1}, \epsilon_{i2}, \dots, \epsilon_{ini})'$ for $i = 1, 2, \dots, a$. Here, the error term $\boldsymbol{\epsilon} = (\boldsymbol{\epsilon}_1, \boldsymbol{\epsilon}_2, \dots, \boldsymbol{\epsilon}_a)'$ is distributed with mean $\mathbf{0}$

and covariance matrix $\eta^2 I$. A vector of 1's with size n_i is denoted by $\mathbf{1}_{ni}$ and a vector of 0's with size n_i by $\mathbf{0}_{ni}$. Substituting Eq. (8) into Eq. (14), this model becomes

$$\mathbf{x} = A\Theta\boldsymbol{\mu}_y + \epsilon.$$

If the transition probability matrix Θ_{ab} is a known full rank matrix and $a \geq b$, we have a full-rank model for which the means of true responses $\boldsymbol{\mu}_y$ can be estimated by the method of least squares. That is, the least square estimator (LSE) is given by

$$\tilde{\boldsymbol{\mu}}_y = \left((A\Theta)' A\Theta \right)^{-1} (A\Theta)' \mathbf{x}. \quad (15)$$

It is interesting to note that LSE is the same as the estimator of Eq. (10). That is,

$$\begin{aligned} \tilde{\boldsymbol{\mu}}_y &= \left((A\Theta)' A\Theta \right)^{-1} (A\Theta)' \mathbf{x} \\ &= \left(\Theta' A' A\Theta \right)^{-1} \Theta' A' \mathbf{x} \\ &= \left(\Theta' \text{diag}(n_1, n_2, \dots, n_a) \Theta \right)^{-1} \Theta' A' \mathbf{x} \\ &= \Theta^{-1} \text{diag}(1/n_1, 1/n_2, \dots, 1/n_a) \Theta^{-1} \Theta' A' \mathbf{x} \\ &= \Theta^{-1} \text{diag}(1/n_1, 1/n_2, \dots, 1/n_a) A' \mathbf{x} \\ &= \Theta^{-1} (\bar{x}_1, \bar{x}_2, \dots, \bar{x}_a)' \\ &= \hat{\boldsymbol{\mu}}_y \end{aligned}$$

if the square matrix Θ is a nonsingular matrix. Suppose $\mathbf{x}$ is distributed $N(A\Theta\boldsymbol{\mu}_y, \eta^2 I)$ and C is $q \times b$ of rank $q \leq b \leq a$. Rencher and Schaafje^[13] shows that the statistic

$$F = \frac{SSH/q}{SSE / \left(\sum_{i=1}^a n_i - b \right)} \quad (16)$$

is distributed as $F\left(q, \sum_{i=1}^a n_i - b\right)$ under $H_0: C\boldsymbol{\mu}_y = 0$, where

$$SSH = (C\tilde{\boldsymbol{\mu}}_y)' \left(C \left((A\Theta)' A\Theta \right)^{-1} C' \right)^{-1} (C\tilde{\boldsymbol{\mu}}_y)$$

and

$$SSE = (\mathbf{x} - A\Theta\tilde{\boldsymbol{\mu}}_y)' (\mathbf{x} - A\Theta\tilde{\boldsymbol{\mu}}_y).$$

The null hypothesis H_0 is rejected at the α level of significance if

$$F = \frac{SSH/q}{SSE / \left(\sum_{i=1}^a n_i - b \right)} > F_{\alpha, q, \sum_{i=1}^a n_i - b},$$

where $F_{\alpha, q, \sum_{i=1}^a n_i - b}$ is the α upper quantile of the F-distribution with q and $\sum_{i=1}^a n_i - b$ degrees of freedom. Under the alternative hypothesis, the test statistic F is distributed as $F_{\alpha, q, \sum_{i=1}^a n_i - b, \lambda}$, where

$$\lambda = \frac{1}{2\eta^2} \boldsymbol{\mu}_y' C' \left(C \left((A\Theta)' A\Theta \right)^{-1} C' \right)^{-1} C \boldsymbol{\mu}_y.$$

If $n_1 = n_2 = \dots = n_a = n$, then $A'A = In$. The non-central parameter becomes

$$\lambda = \frac{1}{2\eta^2} \boldsymbol{\mu}_y' C' \left(C(\Theta'\Theta)^{-1} C' \right)^{-1} C \boldsymbol{\mu}_y. \quad (17)$$

If we have $C, \boldsymbol{\mu}_y, \Theta$ and η^2 , the sample size n can be obtained by solving Eq. (17). Given a, b, α, q and β , the parameter λ can be obtained by solving the following power equation

$$P(F > F_{\alpha, q, na-b} | H_a, \lambda) = 1 - \beta \quad (18)$$

where the random variable F follows the non-central F distribution with degrees of freedom q and $na - b$, and non-centrality parameter λ . However, this power equation cannot be solved for λ because of unknown sample size n . Two unknown parameters n and λ can be obtained by solving two nonlinear Eqs. (17) and (18). Sample size algorithms^[14] is employed to obtain the blind sample size. Given $a, b, \alpha, \beta, C, \boldsymbol{\mu}_y, \Theta$ and η^2 , the following actions should occur to obtain the sample size.

Step 1: Provide an initial sample size.

Step 2: Obtain the critical value $F_{\alpha, q, na-b}$ such that $P(F > F_{\alpha, q, na-b} | H_0) = \alpha$, where the test statistic F follows a central F distribution with degrees of freedom q and $na - b$.

Step 3: Calculate the power $P(F > F_{\alpha, q, na-b} | H_a, \lambda)$, where the random variable F follows the non-central F distribution with degrees of freedom q and $na - b$, and non-centrality parameter $\lambda = \frac{n}{2\eta^2} \boldsymbol{\mu}_y' C' \left(C(\Theta'\Theta)^{-1} C' \right)^{-1} C \boldsymbol{\mu}_y$.

Step 4: If the power in Step 3 is smaller than the desired power $1 - \beta$, increase the sample size by one unit. Otherwise, reduce the sample size by one unit.

Step 5: Do the iterations from Step 2 to Step 4 until the sample size converges.

Non-inferiority or Superiority Trials

The objective of this section is to show that the new treatment is statistically not inferior (or superior) to the standard approved product. The hypothesis of interesting is

$$H_0: \mu_{y1} - \mu_{y2} \leq \delta \quad \text{versus} \quad H_a: \mu_{y1} - \mu_{y2} > \delta$$

where δ is the non-inferiority/superiority margin. When σ_x^2 is known, the null hypothesis H_0 is rejected at the significance level α if

$$\frac{\hat{\mu}_{y1} - \hat{\mu}_{y2} - \delta}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} > Z_\alpha.$$

Rejecting the null hypothesis implies that the treatment mean is greater than the reference mean by at least the margin δ . Under the alternative hypothesis that $H_a: \mu_{y1} - \mu_{y2} > \delta$, the power of the test can be expressed as

$$\begin{aligned} 1 - \beta &= P\left(\frac{\hat{\mu}_{y1} - \hat{\mu}_{y2} - \delta}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} > Z_\alpha\right) \\ &= P\left(Z > Z_\alpha - \frac{\mu_{y1} - \mu_{y2} - \delta}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}}\right) \\ &= P\left(Z < -Z_\alpha + \frac{\mu_{y1} - \mu_{y2} - \delta}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}}\right) \\ &= \Phi\left(-Z_\alpha + \frac{\mu_{y1} - \mu_{y2} - \delta}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}}\right). \end{aligned}$$

The sample size needed to achieve power $1 - \beta$ can be obtained by solving the following equation

$$-Z_\alpha + \frac{\mu_{y1} - \mu_{y2} - \delta}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} = Z_\beta.$$

After some algebra, the blind sample size is given by

$$n = \frac{(z_\alpha + z_\beta)^2}{(\mu_{y1} - \mu_{y2} - \delta)^2} \frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2. \quad (19)$$

Equivalence Trials

The objective of the equivalence study is to test the following hypotheses

$$H_0: |\mu_{y1} - \mu_{y2}| \geq \delta \quad \text{versus} \quad H_a: |\mu_{y1} - \mu_{y2}| < \delta.$$

where δ is the equivalence margin. This is the same as to conduct two one-sided tests simultaneously. That is

$$H_{01}: \mu_{y1} - \mu_{y2} \geq \delta \quad \text{versus} \quad H_{a1}: \mu_{y1} - \mu_{y2} < \delta$$

and

$$H_{02}: \mu_{y1} - \mu_{y2} \leq -\delta \quad \text{versus} \quad H_{a2}: \mu_{y1} - \mu_{y2} > \delta.$$

Suppose σ_x^2 is known. The null hypotheses H_{01} and H_{02} are rejected at the significance level α if

$$\frac{\hat{\mu}_{y1} - \hat{\mu}_{y2} - \delta}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} = -Z_\alpha$$

and

$$\frac{\hat{\mu}_{y1} - \hat{\mu}_{y2} + \delta}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} > Z_\alpha,$$

respectively. Note that there is no need to correct the overall significant level α due to the fact that both null hypotheses are rejected for the equivalent study. Under $H_{a1}: \mu_{y1} - \mu_{y2} < \delta$, the power can be written by

$$\begin{aligned} 1 - \beta &= P\left(\frac{\hat{\mu}_{y1} - \hat{\mu}_{y2} - \delta}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} < -Z_\alpha\right) \\ &= P\left(Z < -Z_\alpha + \frac{\delta - (\mu_{y1} - \mu_{y2})}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}}\right) \\ &= \Phi\left(-Z_\alpha + \frac{\delta - (\mu_{y1} - \mu_{y2})}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}}\right) \end{aligned}$$

Under $H_{a2}: \mu_{y1} - \mu_{y2} > \delta$, the power for the second hypothesis is given by

$$\begin{aligned} \text{power} &= P\left(\frac{\hat{\mu}_{y1} - \hat{\mu}_{y2} + \delta}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} > -Z_\alpha\right) \\ &= P\left(Z > Z_\alpha + \frac{-\delta - (\mu_{y1} - \mu_{y2})}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}}\right) \\ &= P\left(Z < -Z_\alpha + \frac{\delta + \mu_{y1} - \mu_{y2}}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}}\right) \end{aligned}$$

$$= \Phi \left(-Z_{\alpha} + \frac{\delta + \mu_{y1} - \mu_{y2}}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} \right).$$

Under the alternative hypothesis $H_a: |\mu_{y1} - \mu_{y2}| < \delta$, the overall power is given by

$$\begin{aligned} 1 - \beta &= \Phi \left(-z_{\alpha} + \frac{\delta - (\mu_{y1} - \mu_{y2})}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} \right) \\ &\quad + \Phi \left(-z_{\alpha} + \frac{\delta + \mu_{y1} - \mu_{y2}}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} \right) - 1 \\ &\geq 2\Phi \left(-Z_{\alpha} + \frac{\delta - |\mu_{y1} - \mu_{y2}|}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} \right) - 1 \\ &= 1 - \beta \end{aligned}$$

To achieve the desired power $1 - \beta$, the blind sample size can be evaluated by solving the following equation

$$-Z_{\alpha} + \frac{\delta - |\mu_{y1} - \mu_{y2}|}{\sqrt{\frac{2}{(2\theta-1)^2}(\theta^2 + (1-\theta)^2)\sigma_x^2/n}} = Z_{\beta/2}.$$

This leads to

$$n = \frac{(Z_{\alpha} + Z_{\beta/2})^2}{(\delta - |\mu_{y1} - \mu_{y2}|)^2} \frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \sigma_x^2.$$

Example

Suppose we plan to duplicate the clinical trial of chronic dizziness in Taiwan. This study is originally conducted by Yardley et al. (2004)^[17]. It is a single blind randomized, controlled trial with 20 study center in southern England. The objective of this study is to evaluate the effectiveness of nurse-delivered vestibular rehabilitation in primary care for patients with chronic dizziness. One hundred seventy patients with chronic dizziness who were randomly assigned to vestibular rehabilitation or usual medical care. Each patient received 30- to 40-minute appointment with a primary care nurse. The nurse taught the patient exercises to be carried out daily at home, with the support of a treatment booklet. The primary

endpoint is the self-reported dizziness handicap inventory at 6 month. Assuming the treatment difference between the vestibular rehabilitation group and the usual medical care groups is about 5 points difference. There may be considerable the difference between ethnicity which may influence the variability in the forthcoming trial. If the variance is unknown prior to the start the trial, the sample size should be calculated at some point during the study. We now conduct a trial with a sample size re-estimation based on the blinded variance estimation at middle of the study. The blind sample variance based upon 100 evaluable patients is $\hat{\sigma}_x^2 = 200$. Considering the transition probability $\theta = 0.8$, the estimated blind sample size of Eq. (13) with 5% type I error and 80% power is determined by

$$\begin{aligned} \hat{n} &= \frac{(z_{\alpha/2} + z_{\beta})^2}{(\mu_{y1} - \mu_{y2})^2} \frac{2}{(2\theta-1)^2} (\theta^2 + (1-\theta)^2) \hat{\sigma}_x^2 \\ &= \frac{(1.96 + 0.84)^2}{5^2} \frac{2}{(1.6-1)^2} (0.8^2 + (1-0.8)^2) 200 \\ &= 238 \text{ subjects per block.} \end{aligned}$$

SURVIVAL ANALYSIS FOR EXPONENTIAL DISTRIBUTION

Considering the lifetime T and a fixed censoring time $L - a$, where a stands for the entry time. The exact lifetime T will be observed only if $T \leq L - a$. The random variable δ indicates whether the lifetime T is observed or not. That is,

$$\delta = \begin{cases} 1, & \text{if } T \leq L - a \\ 0, & \text{if } T > L - a. \end{cases}$$

The probability density function is $f_T(t) = \lambda e^{-t\lambda}$ if the lifetime T is assumed to be exponentially distributed with the parameter λ . Let $X = \min(T; L - a)$. If $\delta = 1$, then $T \leq L - a$. This implies that $X = \min(T, L - a) = T$. Thus, $f_X(x) = f_T(x) = \lambda e^{-x\lambda}$. If $\delta = 0$, then $T > L - a$. and $X = \min(T, L - a) = L - a$. The survival function of random variable X is given by

$$\begin{aligned} S_X(x) &= P(X > x) \\ &= P(\min(T, L - a) > x) \\ &= P(T > L - a > x) \\ &= \int_x^{\infty} \lambda e^{-t\lambda} dt \\ &= e^{-x\lambda}. \end{aligned}$$

The joint probability density function of the random variables x and δ can be written by

$$g(x, \delta) = \begin{cases} \lambda e^{-x\lambda}, & \text{if } \delta = 1 \\ e^{-x\lambda}, & \text{if } \delta = 0. \end{cases} \quad (20)$$

This is equivalent to state that $g(t, \delta = 1) = \lambda e^{-t\lambda}$ if $0 < t < L$, and $g(t, \delta = 0) = e^{-t\lambda}$ if $0 < L < t$. The function of (20) can be simplified as

$$g(x, \delta) = (\lambda e^{-x\lambda})^\delta (e^{-x\lambda})^{1-\delta} = \lambda^\delta e^{-x\lambda}.$$

Assuming that the entry time a follows the probability density function

$$h(a) = \frac{\gamma e^{-\gamma a}}{1 - e^{-\gamma L_0}}, \quad 0 \leq a \leq L_0.$$

The likelihood function is given

$$L(\lambda) = \frac{\gamma e^{-\gamma a}}{1 - e^{-\gamma L_0}} \lambda^\delta e^{-x\lambda}. \quad (21)$$

Suppose there is n_i subjects of i th block with lifetimes $T_{i1}, T_{i2}, \dots, T_{ini}$ and entry times $a_{i1}, a_{i2}, \dots, a_{ini}$. Each subject has a fixed censoring time $L_{ik} = L - a_{ik} > 0$, where $k = 1, 2, \dots, n_i$ and $i = 1, 2, \dots, g$. If T_{ik} 's are assumed to be independently and identically distributed exponentially with the same parameter λ_{xi} , the likelihood function of λ_{xi} is given by

$$\begin{aligned} L(\lambda_{xi}) &= \prod_{k=1}^{n_i} \frac{\gamma e^{-\gamma a_{ik}}}{1 - e^{-\gamma L_0}} (\lambda_{xi})^{\delta_{ik}} e^{-\lambda_{xi} L_{ik}} \\ &= \frac{\gamma^n e^{-\gamma \sum_{i=1}^g \sum_{k=1}^{n_i} a_{ik}}}{(1 - e^{-\gamma L_0})^n} (\lambda_{xi})^{\sum_{k=1}^{n_i} \delta_{ik}} e^{-\sum_{k=1}^{n_i} \lambda_{xi} L_{ik}}. \end{aligned}$$

Taking the logarithm, we have

$$\begin{aligned} \log L(\lambda_{xi}) &= \log \frac{\gamma^n e^{-\gamma \sum_{i=1}^g \sum_{k=1}^{n_i} a_{ik}}}{(1 - e^{-\gamma L_0})^n} \\ &\quad + \sum_{k=1}^{n_i} \delta_{ik} \log \lambda_{xi} - \sum_{k=1}^{n_i} \lambda_{xi} L_{ik}. \end{aligned} \quad (22)$$

Taking the derivative of Eq. (22) with respect to λ_{xi} and then setting to zero, we have

$$\frac{\partial \log L}{\partial \lambda_{xi}} = \sum_{k=1}^{n_i} \delta_{ik} \frac{1}{\lambda_{xi}} - \sum_{k=1}^{n_i} x_{ik} = 0.$$

Solving for λ_{xi} , the maximum likelihood estimator (MLE) is given by

$$\hat{\lambda}_{xi} = \frac{\sum_{k=1}^{n_i} \delta_{ik}}{\sum_{k=1}^{n_i} x_{ik}}.$$

The Fisher's information can be obtained by taking the second derivative of log function of Eq. (21) firstly

$$\frac{\partial^2 \log L}{\partial \lambda_{xi}^2} = -\frac{\delta_{ik}}{\lambda_{xi}^2}$$

and then taking the expectation. That is,

$$\begin{aligned} I(\lambda_{xi}) &= -E \left(\frac{\partial^2 \log L}{\partial \lambda_{xi}^2} \right) \\ &= E \left(\frac{\delta_{ik}}{\lambda_{xi}^2} \right). \end{aligned}$$

Here

$$\begin{aligned} E(\delta_{ik}) &= \sum_{\delta_{ik}=0}^1 \delta_{ik} P(\delta_{ik}) \\ &= P(\delta_{ik} = 1) \\ &= 1 - P(\delta_{ik} = 0) \\ &= 1 - P(0 < a_i < L_0, T_i > L - a_i) \\ &= 1 - \int_0^{L_0} \int_{L-a_i}^{\infty} \frac{\gamma^n e^{-\gamma a_i}}{1 - e^{-\gamma L_0}} \lambda_{xi} e^{-\lambda_{xi} t_i} dt_i da_i \\ &= 1 - \int_0^{L_0} \frac{\gamma e^{-\gamma a_i}}{1 - e^{-\gamma L_0}} e^{-\lambda_{xi} (L-a_i)} da_i \\ &= 1 + \frac{\gamma e^{-\lambda_{xi} L} \left(1 - e^{(\lambda_{xi} - \gamma) L_0} \right)}{(\lambda_{xi} - \gamma)(1 - e^{-\gamma L_0})}. \end{aligned}$$

The variance for $\hat{\lambda}_{xi}$ is

$$V(\hat{\lambda}_{xi}) = \frac{1}{I(\lambda_{xi})} = \frac{\hat{\lambda}_{xi}^2}{\hat{E}(\delta_{ik})} = \frac{\lambda_{xi}^2}{\gamma e^{-\lambda_{xi} L} \left(1 - e^{(\lambda_{xi} - \gamma) L_0} \right) + (\lambda_{xi} - \gamma)(1 - e^{-\gamma L_0})}.$$

When $\gamma = 0$, we define $h(a) = 1/L_0$. Then

$$E(\delta_{ik}) = \frac{e^{-\lambda_{xi} L} - e^{\lambda_{xi} (L-L_0)}}{\lambda_{xi} L_0}. \text{ Consequently,}$$

$$V(\lambda_{xi}) = \frac{1}{I(\lambda_{xi})} = \frac{\lambda_{xi}^2}{\hat{E}(\delta_{ik})} = \frac{\lambda_{xi}^2}{1 + \frac{e^{-\lambda_{xi} L} - e^{-\lambda_{xi} (L-L_0)}}{\lambda_{xi} L_0}}.$$

By Slutsky's theorem, the MLE satisfies

$$\sqrt{n_i} (\hat{\lambda}_{xi} - \lambda_{xi}) \xrightarrow{D} N(0, V(\hat{\lambda}_{xi})).$$

Letting $\lambda_x = (\lambda_{x1}, \lambda_{x2}, \dots, \lambda_{xg})'$ and $n_1 = n_2 = \dots = n_g = n$, we have

$$\sqrt{n} (\hat{\lambda}_x - \lambda_x) \xrightarrow{D} N(0, V(\hat{\lambda}_x))$$

where $V(\hat{\lambda}_x) = \text{diag}(V(\hat{\lambda}_{x1}), \dots, V(\hat{\lambda}_{xg}))$. Considering the transition probability matrix model

$$\lambda_x = \Theta \lambda_y,$$

Where $\lambda_y = (\lambda_{y1}, \lambda_{y2}, \dots, \lambda_{yg})'$ and the transition probability matrix

$$\Theta = \begin{pmatrix} \theta_{11} & \theta_{12} & \cdots & \theta_{1g} \\ \theta_{21} & \theta_{22} & \cdots & \theta_{2g} \\ \vdots & \vdots & \ddots & \vdots \\ \theta_{g1} & \theta_{g2} & \cdots & \theta_{gg} \end{pmatrix}$$

If the transition probability matrix Θ is a nonsingular matrix, then

$$\lambda_y = \Theta^{-1} \lambda_x.$$

Hence,

$$\sqrt{n} \left(C \hat{\lambda}_y - C \lambda_y \right) \xrightarrow{D} N \left(0, C \Theta^{-1} V \left(\hat{\lambda}_x \right) \Theta^{-1'} C' \right)$$

where C is a known $q \times g$ coefficient matrix of rank $q \leq g$. In particular, if $g = 2$, $C = (1 \ -1)$ and $\theta_{11} = \theta_{12} = \theta$, then

$$\sqrt{n} \left(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} - (\lambda_{y1} - \lambda_{y2}) \right) \xrightarrow{D} N \left(0, V \left(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} \right) \right).$$

Hence,

$$\begin{aligned} V \left(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} \right) &= C \Theta^{-1} V \left(\hat{\lambda}_x \right) \Theta^{-1'} C' \\ &= \frac{1}{(2\theta - 1)^2} \left(V \left(\hat{\lambda}_{x1} \right) + V \left(\hat{\lambda}_{x2} \right) \right) \end{aligned}$$

We reject the null hypothesis $H_0 : \lambda_{y1} = \lambda_{y2}$ at the α level of significance if

$$\sqrt{n} \left| \frac{\hat{\lambda}_{y1} - \hat{\lambda}_{y2}}{\sqrt{V \left(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} \right)}} \right| > Z_{\alpha/2}$$

Under the alternative hypothesis $H_a : \lambda_{y1} \neq \lambda_{y2}$, the power of the above test is approximately

$$\Phi \left(\frac{\sqrt{n} (\lambda_{y1} - \lambda_{y2})}{\sqrt{V \left(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} \right)}} - Z_{\alpha/2} \right).$$

As a result, the sample size needed for achieving a power of $1 - \beta$ can be obtained by the following equation:

$$\frac{\sqrt{n} (\lambda_{y1} - \lambda_{y2})}{\sqrt{V \left(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} \right)}} - Z_{\alpha/2} = Z_{\beta}.$$

This leads to

$$\begin{aligned} n &= V \left(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} \right) \left(\frac{Z_{\alpha/2} + Z_{\beta}}{\lambda_{y1} - \lambda_{y2}} \right)^2 \\ &= \frac{1}{(2\theta - 1)^2} \left(V \left(\hat{\lambda}_{x1} \right) + V \left(\hat{\lambda}_{x2} \right) \right) \left(\frac{Z_{\alpha/2} + Z_{\beta}}{\lambda_{y1} - \lambda_{y2}} \right)^2 \end{aligned}$$

where

$$V \left(\hat{\lambda}_{x_i} \right) = \frac{\lambda_{x_i}^2}{\gamma e^{-\lambda_{x_i} L} \left(1 - e^{(\lambda_{x_i} - \gamma) L_0} \right) + \frac{1}{(\lambda_{x_i} - \gamma)(1 - e^{-\gamma L_0})}}$$

for $i = 1, 2$.

Non-inferiority or Superiority Trials

Let λ_{y1} and λ_{y2} are the hazard rates of the control and test drug, respectively. A smaller hazard rate is considered in favor of the test drug. The hypothesis for the superiority/non-inferiority is given by

$$H_0 : \lambda_{y1} - \lambda_{y2} \leq \delta$$

versus the alternative hypothesis

$$H_a : \lambda_{y1} - \lambda_{y2} > \delta$$

where δ stands for the superiority or non-inferiority margin. The non-inferiority test is to show that the new treatment is at least as good as the approved product. The superiority test is to show that the new treatment is better than the standard product.

We reject the null hypothesis $H_0 : \lambda_{y1} - \lambda_{y2} \leq \delta$ at the α level of significance if

$$\frac{\sqrt{n} \left(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} - \delta \right)}{\sqrt{V \left(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} \right)}} > Z_{\alpha}.$$

Rejection of the null hypothesis indicates that the test drug is superior to the standard treatment if the margin $\delta > 0$ or the test drug is non-inferior to the standard treatment if the margin $\delta < 0$. Under the alternative hypothesis $H_a : \lambda_{y1} - \lambda_{y2} > \delta$, the power of the above test is approximately

$$\Phi \left(\frac{\sqrt{n} (\lambda_{y1} - \lambda_{y2} - \delta)}{\sqrt{V \left(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} \right)}} - Z_{\alpha} \right).$$

As a result, the sample size needed for achieving a power of $1 - \beta$ can be obtained by the following equation:

$$\frac{\sqrt{n} (\lambda_{y1} - \lambda_{y2} - \delta)}{\sqrt{V \left(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} \right)}} - Z_{\alpha} = Z_{\beta}.$$

After some algebra, this leads to

$$n = V(\hat{\lambda}_{y1} - \hat{\lambda}_{y2}) \left(\frac{Z_\alpha + Z_\beta}{\lambda_{y1} - \lambda_{y2} - \delta} \right)^2$$

$$= \frac{1}{(2\theta - 1)^2} \left(V(\hat{\lambda}_{x1}) + V(\hat{\lambda}_{x2}) \right) \left(\frac{Z_\alpha + Z_\beta}{\lambda_{y1} - \lambda_{y2} - \delta} \right)^2.$$

Equivalence Trials

The new treatment is equivalent to the standard product.

The hypothesis we are interested in the equivalence trial is given by

$$H_0: |\lambda_{y1} - \lambda_{y2}| \geq \delta \quad \text{versus} \quad H_a: |\lambda_{y1} - \lambda_{y2}| < \delta$$

where δ stands for the equivalence margin. Breaking up the absolute values in the original hypothesis into two one-sided tests, we reject the null hypothesis at the α level of significance if

$$\frac{\sqrt{n}(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} - \delta)}{\sqrt{V(\hat{\lambda}_{y1} - \hat{\lambda}_{y2})}} < -Z_\alpha$$

and

$$\frac{\sqrt{n}(\hat{\lambda}_{y1} - \hat{\lambda}_{y2} - \delta)}{\sqrt{V(\hat{\lambda}_{y1} - \hat{\lambda}_{y2})}} > Z_\alpha.$$

Under the alternative hypothesis $H_a: |\lambda_{y1} - \lambda_{y2}| < \delta$, the power of the above test is approximately

$$2\Phi \left(\frac{\sqrt{n}(\delta - |\lambda_{y1} - \lambda_{y2}|)}{\sqrt{V(\hat{\lambda}_{y1} - \hat{\lambda}_{y2})}} - Z_\alpha \right) - 1.$$

As a result, the sample size needed for achieving a power of $1 - \beta$ can be obtained by the following equation:

$$\frac{\sqrt{n}(\delta - |\lambda_{y1} - \lambda_{y2}|)}{\sqrt{V(\hat{\lambda}_{y1} - \hat{\lambda}_{y2})}} - Z_\alpha = Z_{\beta/2}.$$

After some algebra, this leads to

$$n = V(\hat{\lambda}_{y1} - \hat{\lambda}_{y2}) \left(\frac{Z_\alpha + Z_{\beta/2}}{\delta - |\lambda_{y1} - \lambda_{y2}|} \right)^2$$

$$= \frac{1}{(2\theta - 1)^2} \left(V(\hat{\lambda}_{x1}) + V(\hat{\lambda}_{x2}) \right)$$

$$\times \left(\frac{Z_\alpha + Z_{\beta/2}}{\delta - |\lambda_{y1} - \lambda_{y2}|} \right)^2.$$

Example

Suppose that a sponsor is planning to conduct a two-stage adaptive design trial to investigate a new treatment against the control. That is to select patient population at the first stage and then at the second stage to confirm the efficacy based on the hazard ratio between treatment and control. An interim analysis is planned to evaluate the sample size when this study is completed at the first stage. This trial at the second stage is designed to last for 3 years ($L = 3$) years with 1 year accrual ($L_0 = 1$). Assuming that uniform patient entry for both groups. That is, $\gamma = 0$. The sample variance of $\hat{\lambda}_{x_i}$ is given by

$$\hat{V}(\hat{\lambda}_{x_i}) = \frac{\hat{\lambda}_{x_i}^2}{1 + \frac{e^{-\hat{\lambda}_{x_i}L} - e^{-\hat{\lambda}_{x_i}(L-L_0)}}{\hat{\lambda}_{x_i}L_0}}.$$

Assuming that the hazard rates are $\lambda_{y1} = 1$ and $\lambda_{y2} = 2$ for the treatment group and control group, respectively. At the end of first stage, we have the sample hazard rates $\hat{\lambda}_{x1} = 1.1$ and $\hat{\lambda}_{x2} = 1.9$. The corresponding variances are $\hat{V}(\hat{\lambda}_{x1}) = 1.30$ and $\hat{V}(\hat{\lambda}_{x2}) = 3.65$. If the transition probability $\theta = 0.8$, the sample size for the second stage is calculated by

$$\hat{n} = \frac{1}{(2\theta - 1)^2} \left(\hat{V}(\hat{\lambda}_{x1}) + \hat{V}(\hat{\lambda}_{x2}) \right) \left(\frac{Z_{\alpha/2} + Z_\beta}{\lambda_{y1} - \lambda_{y2}} \right)^2$$

$$= \frac{1}{(2 \times 0.8 - 1)^2} (1.30 + 3.65) \left(\frac{1.96 + 1.28}{2 - 1} \right)^2$$

$$= 145 \text{ per block.}$$

CONCLUSION

In clinical trial, the interim analyses should be specified in the protocol if there is ethical and/or economic concern. Tharmanathan et al.^[15] point out a significant rise in the number of trials reporting use of interim analysis over last decade. An independent Data Monitoring Committee is usually established to review the interim analysis results and make recommendations to the sponsor about any action needed based on unblind results. It becomes a challenge problem if the sponsor itself plans to re-evaluate the sample size without breaking the blind in the middle of trial. It is achievable using the released data that contains the primary response and the randomization block. The transition probability matrix plays a central role in this setting. The transition probability matrix is essentially a transformation matrix between the treatment groups and the randomization blocks. A randomization scheme is desired to obtain the treatment allocation ratios of this matrix. The sample size is getting smaller as this matrix approaches to the identity matrix. The sample size also depends on the hypothesis. The calculated sample size for a non-inferiority trial is usually the smallest of the three hypothesis. The superiority comparison will have a sample

size that is much larger. In general, a equivalence trial will have a sample size that is larger than a non-inferiority trial. It must beware of $\mu_1 - \mu_2 > \delta$ for the sample size calculation of the non-inferiority or superiority trial.

In the balanced design with two treatments and two blocks, the blind sample size is comparable to the unblind sample size in terms of mean and variance. Stratified randomization for setting a probability transition matrix is recommended where the randomization scheme is performed separately within each dummy stratum, which is proposed by Shih and Zhao^[3]. For example, suppose equal allocation is planned in a two-armed trial (treatment A and B). If the patients are assigned to treatment A with specified probabilities, say 2/3 and 1/3, for first dummy stratum and second dummy stratum, respectively, the transition probability matrix here is $\Theta = \begin{pmatrix} 2/3 & 1/3 \\ 1/3 & 2/3 \end{pmatrix}$.

The randomization procedure is designed as follows. A block size of 12 with an allocation ratio of 2:1 would lead to random assignment of 8 subjects to treatment A and 4 to the treatment B for first stratum, vice versa for second stratum. The subjects are randomly assigned to either treatment A or B with equal probability by swapping over stratum 1 and 2. In this situation, the randomization plan may look like:

Stratum 1: AABABAAAABAB... for odd number of patients.

Stratum 2: ABBBABABABBB... for even number of patients.

The treatments for first 24 patients are AAABBBABBBAA BAAABAABBABBB...

Abstract

Blinding is an approach used in clinical trials meant to eliminate bias by blocking the identity of treatments. This entry focuses on different types of clinical trial blinding and discusses the importance of this practice in obtaining honest results.

INTRODUCTION

Although randomization is used to prevent bias from a statistical assessment of the study drug, it does not guarantee that there will be no bias caused by subjective judgment in reporting, evaluation, data processing, and statistical analysis. This subjectivity is a result of the knowledge of the identity of the treatments. Because this subjective and judgmental bias is directly or indirectly related to treatment, it can seriously distort statistical inference on the treatment effect. In practice, it is extremely difficult to quantitatively assess such bias and its impact on the assessment of the treatment effect. In clinical trials, it is therefore important to consider an approach to eliminate such bias by blocking the identity of treatments. Such an approach is referred to as blinding.

TYPES OF BLINDING

Blinding in clinical trials can be classified into four types: open label, single blind, double blind, and triple blind.^[1]

Open Label

An open-label study is a clinical trial where no blinding is employed; that is, both the investigators and the patients know which treatment the patients receive. Because patients may psychologically react in favor of the treatments if they are aware of which treatment they receive, serious bias may eventually occur. Therefore open-label trials are generally not recommended for comparative clinical trials. In current practice, open-label trials are not accepted as adequate, well-controlled clinical trials for providing substantial evidence for approval by most regulatory agencies including the Food and Drug Administration (FDA). However, under certain circumstances, open-label trials are necessary. Spilker^[2] provided a list of situations

and circumstances in which open-label trials may be conducted. Ethical consideration is always an important factor, or perhaps the only factor that is used to determine whether a trial should be conducted in an open-label fashion. For example, Phase I studies on dose escalation for the determination of the maximum tolerable dose of drugs in treating terminally ill cancer patients are usually open-labeled. Clinical trials for evaluation of the effectiveness and safety of a new surgical procedure are usually conducted in an open-label fashion. This is because it is clearly unethical to conduct a double-blind trial with a concurrent control group in which patients are incised under a general anesthesia to stimulate the surgical procedure. Note that premarketing and postmarketing surveillance studies are usually open-labeled. The purpose of premarketing surveillance studies is to collect the data of efficacy and safety with respect to the duration of exposure of a broader patient population to the test drug, while the objective of postmarketing surveillance studies is to monitor the safety and tolerability of the drug product.

Single Blind

In practice, a single-blind trial is referred to as a trial in which the patient's treatment assignment is not known to the patient only. As compared with open-label trials, single-blind studies offer a certain degree of control and the assurance of the validity of clinical trials. However, by knowing which treatment the patients receive, the investigator's clinical evaluation may be biased.

Double Blind

A double-blind trial is a trial in which neither the patients nor the investigators (study centers) are aware of patients' treatment assignment. Note that the "investigator" could mean all of the health-care personnel, which include the study center, the contract laboratories, and the other

consulting experts for evaluation of effectiveness and safety of patients in a broader sense. In addition to the patients and the investigators, if all members of clinical project team associated with the study are also blinded, then the clinical trial is said to be triple blinded. These members include the project clinicians, clinical research associates (CRA), statisticians, programmers, and data coordinators. In addition to patients’ treatment assignment, the blindness also applies to concealment of the overall results of the trial. In practice, although the project clinicians, CRA, statisticians, programmers, and data coordinators usually have access to the individual patient’s data, they are generally not aware of the treatment assignment for each patient. In addition, the overall treatment results, if any (such as interim analyses), will not be made available to the patients, the investigators, the project clinicians, CRA, statisticians, programmers, and data coordinators until a decision is made at an appropriate time.

Triple Blind

A triple-blind study with respect to blindness can provide the highest degree for the validity of a controlled clinical trial. Hence it provides the most conclusive unbiased evidence for the evaluation of the effectiveness and safety of the therapeutic intervention under investigation.

Note that triple blinding is generally reserved for large cooperative, multicenter studies monitored by a committee; however, it has been applied to company monitors to ensure they remain unaware of treatment allocation. For the current practice, double blinding has become a gold standard for clinical research because it provides the greatest probability for reducing bias.

THE INTEGRITY OF BLINDING

In practice, even with the best intentions for preserving blindness throughout a clinical trial, blindness can sometimes be breached for various reasons. One method to determine whether the blindness is seriously violated is to ask patients to guess their treatment codes during the study or at the conclusion of the trial prior to unblinding. In some cases, investigators are also asked to guess the patients’ treatment codes. Once the guesses are recorded on the case report forms and entered into the database, the integrity of blinding can be tested. When the integrity of blinding is doubtful, adjustments to statistical analysis should be made.

Data on guessing treatment codes are typically of the form given in Tables 1 and 2 in the following two examples.

The first example is a 1-year double-blind placebo-controlled study conducted by the National Institutes of Health to evaluate the distinguish between the prophylactic and therapeutic effects of ascorbic acid for the common

cold.^[3] A two-group parallel design was used. At the completion of the study, a questionnaire was distributed to everyone enrolled in the study so that they could guess which treatment they had been taking. Results from the 190 subjects who completed the study are given in Table 1.

The second example is a double-blind placebo-controlled trial with a two-group parallel design for evaluation of the effectiveness of an appetite suppressant in weight loss in obese women.^[4] Table 2 lists the data on patients’ guesses of the treatment codes.

To test the integrity of blinding, we need to define a null hypothesis H_0 . Consider a single-site parallel design comparing $a \geq 2$ treatments. Let A_i be the event that a patient guesses that he/she is in the i th group, $i = 1, \dots, a$. Let $A_a + 1$ be the event that a patient does not guess (or answers “do not know”). Finally, let B_j be the event that a patient is assigned to the j th group, $j = 1, \dots, a$. If the hypothesis

$H_0: A_i \text{ and } B_j \text{ are independent for any } i \text{ and } j$

holds, then the blindness is considered to be preserved. The hypothesis H_0 can be tested using the well-known Pearson’s chi-square test under the contingency tables constructed based on observed counts such as those given by Tables 1 and 2. Analysis on investigators’ guesses of patients’ treatment codes can be similarly performed.

A straightforward calculation using data in Tables 1 and 2 results in observed Pearson’s chi-square statistics 31.3 and 22.5, respectively. Thus the null hypothesis of independence of A_i and B_j is rejected at a very high significance level (the p values are smaller than 0.001). That is, in both examples, the blindness is not preserved.

Table 1 Results of Patients’ Guess on Treatment for the Prophylactic Use

Patient’s guess	Actual assignment	
	Ascorbic acid	Placebo
Ascorbic acid	40	11
Placebo	12	39
Do not know	49	39
Total	101	89

From Ref. [3].

Table 2 Results of Patients’ Guess on Treatment for Weight Loss

Patient’s guess	Actual assignment	
	Active drug	Placebo
Active drug	19	3
Placebo	3	16
Do not know	2	6
Total	24	25

From Ref. [4].

ANALYSIS UNDER BREACHED BLINDNESS

When the test of the integrity of blinding resulted in a significant result, analyzing data by ignoring this result may lead to a biased result; that is, the integrity of blinding is doubtful. In what follows, we introduce a method of testing treatment effects by incorporating the data of patients' guesses of their treatment codes.^[5] The idea is to include patient's guess as a factor in the analysis of variance (ANOVA) for the treatment effects.

Suppose that the study design is a single-site parallel design comparing $a \geq 2$ treatments. If the blindness is preserved, then treatment effects can be tested using the one-way ANOVA. Let γ be the factor of guessing treatment codes, which has b levels. Including factor γ in the analysis with patients' guessing data and assuming that patients' guessing is independent of their response value, we can test treatment effects by using a two-way ANOVA. If the study is a multicenter trial, then including factor γ leads to a three-way ANOVA.

There are different ways to construct the variable γ . One way is to use guessing treatment $i, i = 1, \dots, a$, as the first a levels of γ and not guessing (do not know) as the last level. Hence $b = a + 1$. Another way is to use guessing correctly, guessing incorrectly, and not guessing as three levels for γ and thus $b = 3$.

Even if the original design is balanced, i.e., each treatment (and center) has the same number of patients, the two-way ANOVA or three-way ANOVA after including factor γ is not balanced. Hence methods for unbalanced ANOVA are necessarily considered. In the following, we illustrate the idea using a single study site, i.e., two-way ANOVA.

Let x_{ijk} be the response from the k th patient under the i th treatment with the j th guessing status, where $i = 1, \dots, a, j = 1, \dots, b, k = 1, \dots, n_{ij}$ and n_{ij} is the number of patients in the (i, j) th cell. Let $\bar{x}_{ij}$ be the sample mean of the patients in the (i, j) th cell, $\bar{x}_i$ be the sample mean of the patients under treatment i , $\bar{x}_j$ be the sample mean of patients with guessing status j , $\bar{x}$ be the sample mean of all patients n_j be the number of patients under treatment i , n_j be the number of patients with guessing status j , and n be the total number of patients. Define

$$R(\mu) = n\bar{x}^2$$

$$R(\mu, \tau) = \sum_{i=1}^a n_i \bar{x}_i^2$$

where τ denotes treatment effect and μ denotes the overall mean,

$$R(\mu, \gamma) = \sum_{j=1}^b n_j \bar{x}_j^2$$

$$R(\mu, \tau, \gamma, \tau \times \gamma) = \sum_{i=1}^a \sum_{j=1}^b n_{ij} \bar{x}_{ij}^2$$

where $\tau \times \gamma$ denotes the interaction between τ and γ , and

$$R(\mu, \tau, \gamma) = \sum_{i=1}^a n_i \bar{x}_{i-}^2 + Z' C^{-1} Z$$

where Z is a $(b-1)$ vector whose j th component is

$$n_{.j} \bar{x}_{.j} - \sum_{i=1}^a n_{ij} \bar{x}_{i-}, \quad j = 1, \dots, b-1$$

and C is a $(b-1) \times (b-1)$ matrix whose j th diagonal element is

$$n_{.j} - \sum_{i=1}^a n_{ij}^2 / n_i$$

and (j, l) th off-diagonal element is

$$- \sum_{i=1}^a n_{ij} n_{il} / n_i$$

Let

$$R(\tau \times \gamma \mid \mu, \tau, \gamma) = R(\mu, \tau, \gamma, \tau \times \gamma) - R(\mu, \tau, \gamma)$$

$$R(\tau \mid \mu) = R(\mu, \tau) - R(\mu)$$

$$R(\gamma \mid \mu) = R(\mu, \gamma) - R(\mu)$$

$$R(\tau \mid \mu, \gamma) = R(\mu, \tau, \gamma) - R(\mu, \gamma)$$

$$R(\gamma \mid \mu, \tau) = R(\mu, \tau, \gamma) - R(\mu, \tau)$$

$$SSE = \sum_{i=1}^a \sum_{j=1}^3 \sum_{k=1}^{n_{ij}} x_{ijk}^2 - R(\mu, \tau, \gamma, \tau \times \gamma)$$

and s be the number of nonzero n_{ij} s. An ANOVA table according to Searle^[6] can be constructed (Table 3).

An F ratio (in the last column of Table 3) is said to be significant at the α level if it is larger than the $(1 - \alpha)$ th quantile of the F distribution with denominator degrees of freedom $n - s$ and the numerator degrees of freedom given by the number in the third column of the same row. Note that $F(\tau \mid \mu)$ is the F ratio for testing τ effect (treatment effect) adjusted for μ and ignoring γ , whereas $F(\tau \mid \mu, \gamma)$ is the F ratio for testing τ effect adjusted for both μ and γ . These two F ratios are the same in a balanced model but are different in an unbalanced model. Similar discussion can be made for $F(\gamma \mid \mu)$ and $F(\gamma \mid \mu, \tau)$.

Because of its imbalance, the interpretation of the results given by F ratios in the ANOVA table is not straightforward. Consider first the case where the interaction $F(\tau \times \gamma \mid \mu, \tau, \gamma)$ is not significant. Table 4 lists a total of 14 possible cases according to the significance of F ratios $F(\tau \mid \mu)$, $F(\tau \mid \mu, \gamma)$, $F(\gamma \mid \mu)$, and $F(\tau \mid \mu)$. The suggestion from Searle^[6] regarding which effects should

be included in the model is given in the second-last column of Table 4. However, our purpose is slightly different; that is, we are interested in whether the treatment effect τ is significant regardless of the presence of the effect γ . Our recommendations in these 14 cases are given in the last column of Table 4, which is interpreted as follows. When both $F(\tau|\mu)$ and $F(\tau|\mu, \gamma)$ are significant (the first 4 rows of Table 4), regardless of whether γ effect is significant or not, the conclusion is easy to make; that is, the treatment effect is significant. In the next three cases (rows 5–7 of Table 4), $F(\tau|\mu)$ is not significant but $F(\tau|\mu, \gamma)$

is significant, indicating that the treatment effect cannot be clearly detected by ignoring γ but once γ is included in the model as a blocking variable, the treatment effect is significant. In these three cases we conclude that the treatment effect is significant. When $F(\tau|\mu, \gamma)$ is not significant but $F(\gamma|\mu)$ is significant, it indicates that once γ is fitted into the model, the treatment effect is not significant; that is, the treatment effect is distorted by the γ effect. In such cases (rows 8–11 in Table 4), we cannot conclude that the treatment effect is significant. In the last three cases (rows 12–14 of Table 4), both $F(\gamma|\mu)$ and $F(\tau|\mu, \gamma)$ are

not significant. If $F(\tau|\mu)$ is significant but $F(\gamma|\mu, \tau)$ is not (row 12 of Table 4), it indicates that γ has no effect and the treatment effect is significant. On the other hand, if $F(\gamma|\mu, \tau)$ is significant but $F(\tau|\mu)$ is not (row 13 of Table 4; a case “should happen somewhat infrequently” according to Ref. [6]), we cannot conclude that the treatment effect is significant. Finally, when neither $F(\tau|\mu)$ nor $F(\gamma|\mu, \tau)$ is significant, then neither treatment effect nor γ effect is significant (row 14 of Table 4).

The analysis is difficult when the interaction $F(\tau \times \gamma|\mu, \tau, \gamma)$ is significant. In general, we cannot conclude that the treatment effect is significant when $F(\tau \times \gamma|\mu, \tau, \gamma)$ is significant. Analysis conditional on the value of γ may be carried out to draw some partial conclusions. An illustration is given in the following example.

AN EXAMPLE

Observed mean weight loss (in kilograms) in the problem of the effectiveness of an appetite suppressant in weight loss in obese women^[4] is shown in Table 5. Recall that the analysis in “The Integrity of Blinding” shows that in this example, the blindness is not preserved with a high significance.

Source	R	df	R/df	F ratio	p value
τ after μ	$R(\tau \mu)$	1	160.2	6.43	0.015
y after μ and τ	$R(y \mu, \tau)$	2	47.2	1.90	0.0162
y after μ	$R(y \mu)$	2	41.9	1.68	0.198
τ after μ and y	$R(\tau \mu, y)$	1	17.9	0.72	0.401
Interaction	$R(\tau \times y \mu, \tau, y)$	2	61.3	2.46	0.907
Error	SSE	43	24.9		

First, consider the analysis with y = guessing correctly, guessing incorrectly, and not guessing. Then,

$\bar{x}_{11} = 9.6$	$n_{11} = 19$	$\bar{x}_{21} = 6.1$	$n_{21} = 16$
$\bar{x}_{12} = 3.9$	$n_{12} = 3$	$\bar{x}_{22} = 2.6$	$n_{22} = 3$
$\bar{x}_{13} = 12.2$	$n_{13} = 2$	$\bar{x}_{23} = 5.8$	$n_{23} = 6$
$\bar{x}_{1..} = 9.1$	$n_{1..} = 24$	$\bar{x}_{2..} = 8.0$	$n_{2..} = 35$
$\bar{x}_{2..} = 5.6$	$n_{2..} = 25$	$\bar{x}_{3..} = 3.3$	$n_{3..} = 6$
$\bar{x} = 7.3$	$n = 49$	$\bar{x}_3 = 7.4$	$n_3 = 8$

The resulting ANOVA table (see Table 3) is given by

Source	R	df	R/df	F ratio	p value
τ after μ	$R(\tau \mu)$	1	160.2	6.43	0.015
y after μ and τ	$R(y \mu, \tau)$	2	72.1	2.90	0.066
y after μ	$R(y \mu)$	2	32.6	1.31	0.280
τ after μ and y	$R(\tau \mu, y)$	1	115.2	4.63	0.037
Interaction	$R(\tau \times y \mu, \tau, y)$	2	12.6	0.51	0.604
Error	SSE	43	24.3		

It seems that the interaction $F(\tau \times \gamma|\mu, \tau, \gamma)$ is not significant and both treatment-effect F ratios $F(\tau|\mu)$ and $F(\tau|\mu, \gamma)$ are significant. Thus according to the previous discussion (see Table 4), we can conclude that the treatment effect is significant, regardless of whether the effect of γ is significant or not.

However, the conclusion may be different if we consider the levels of γ to be guessing active drug, guessing placebo, and not guessing. With this choice of levels of γ , the sample means are given by

$\bar{x}_{11} = 9.6$	$n_{11} = 19$	$\bar{x}_{21} = 2.6$	$n_{21} = 3$
$\bar{x}_{12} = 3.9$	$n_{12} = 3$	$\bar{x}_{22} = 6.2$	$n_{22} = 16$
$\bar{x}_{13} = 12.2$	$n_{13} = 2$	$\bar{x}_{23} = 5.8$	$n_{23} = 6$
$\bar{x}_{1..} = 9.1$	$n_{1..} = 24$	$\bar{x}_{2..} = 8.7$	$n_{2..} = 22$
$\bar{x}_{2..} = 5.6$	$n_{2..} = 25$	$\bar{x}_{3..} = 5.7$	$n_{3..} = 19$
$\bar{x} = 7.3$	$n = 49$	$\bar{x}_3 = 7.4$	$n_3 = 8$

Note that $\bar{x}_{1i}$ are unchanged but $\bar{x}_{2j}$ are changed with this new choice of levels of γ . The corresponding ANOVA table is given at the bottom of the page.

Although $F(\tau|\mu)$ remains the same, the value of $F(\tau \times \gamma|\mu, \tau, \gamma)$ is much larger than that in the previous case. The p value corresponding to $F(\tau \times \gamma|\mu, \tau, \gamma)$ is 0.097, which indicates that the interaction between the treatment and γ is marginally significant. If this interaction is ignored, then we may conclude that the treatment effect is significant because the only significant F ratio is $F(\tau|\mu)$. But no conclusion can be made if the interaction effect cannot be ignored. In the presence of interaction, a subgroup analysis (according to the levels of γ) may be useful.

Subgroup sample mean comparisons can be made as indicated in Fig. 1. Figure 1 displays six subgroup sample means $\bar{x}_{ij}, i = 1, 2, j = 1, 2, 3$. Fig. 1(A) considers the situation where γ = guessing correctly, guessing incorrectly, and not guessing, while Fig. 1(B) considers the situation where γ = guessing active drug, guessing placebo, and not guessing. The two sample means (dots) corresponding to the same γ level are connected by a straight line segment. In part (A) of the figure, although the three line segments have different slopes, the slopes have the same sign; furthermore, every pair of two line segments either does not cross or crosses slightly. This indicates that in the situation considered by part (A) of the figure, there is no significant

Fig. 1 Subgroup sample mean comparison

interaction and the treatment effect is evident. On the other hand, the slopes of the line segments in part (B) of Fig. 1 have different signs and two line segments considerably cross, which indicates that the interaction is significant and that we cannot draw an overall conclusion on the treatment effect in the situation considered by part (B) of the figure.

Abstract

This entry details the bootstrap approach to statistical analysis by providing several examples of this method to test its validity and applications.

INTRODUCTION

The process of a statistical analysis based on a set of observed data can be briefly described as follows. We believe that the observed data are from a postulated (parametric or nonparametric) model. Unknown quantities in the postulated model are estimated based on the observed data. Estimators are assessed using some accuracy measures (e.g., variance or mean squared error), and further inference may be made based on these estimators and their accuracy measures and/or distributional properties.

OVERVIEW

In the traditional approach, accuracy measures and distributions of estimators are estimated by first deriving their theoretical (approximate) formulas and then by estimating unknown quantities in these formulas. The derivations involved may be difficult, complicated, and/or tedious. For example, when the chosen estimator is $g(\bar{X})$, where $\bar{X}$ is the sample mean of some independent and identically distributed (iid) random vectors and g is a differentiable function, applying Taylor's expansion and the Central Limit Theorem leads to approximate formulas of the variance and the distribution of $g(\bar{X})$, i.e., $g(\bar{X})$ is approximately normally distributed with a mean of $g(\mu)$ and a variance of $[\nabla g(\mu)]'V(\bar{X})\nabla g(\mu)$, where ∇g is the vector of partial derivatives of g , $\mu = E(\bar{X})$, and $V(\bar{X})$ is the variance–covariance matrix of $\bar{X}$. The derivation of ∇g may be quite involved if the problem is high-dimensional and the function g is defined implicitly or in a complicated manner. As an example, consider the estimation of the poverty line (low income cutoff) of the population in the study of income shares or wealth distributions. For the i th sampled family, let z_i be the expenditure on necessities, let y_i be the total income, and let x_{it} ($t = 1, \dots, T$) be the variables such as urbanization category and family size. Then:

$$\log z_i = \gamma_1 + \gamma_2 \log y_i + \sum_{t=1}^T \beta_t x_{it} + \text{error} \quad (1)$$

where γ and β are unknown parameters. Let γ_0 be the overall proportion of income spent on necessities. Then the poverty line θ can be defined as the solution of:

$$\log[(\gamma_0 + 0.2)\theta] = \gamma_1 + \gamma_2 \log \theta + \sum_{t=1}^T \beta_t x_{0t} \quad (2)$$

for a particular set of $x_{01}, \dots, x_{0T}$.^[1] Suppose that the regression parameters in Eq. 1 are estimated by the least squares estimators $\hat{\gamma}_j$ and $\hat{\beta}_t$ and γ_0 is estimated by $\bar{z}/\bar{y}$, where $\bar{z}$ and $\bar{y}$ are the sample means of z_i and y_i , respectively. Then a natural estimator $\hat{\theta}$ of θ is the solution of Eq. 2 with γ_j and β_t replaced by $\hat{\gamma}_j$ and $\hat{\beta}_t$, respectively. Let $X_i = (z_i, y_i, \log z_i, \log y_i, x_{i1}, \dots, x_{iT})$. Then $\hat{\theta}$ can be written as $g(\bar{X})$ for an implicit function g . The derivation of ∇g is complicated. Even if g is not implicit, the derivation of the derivatives is tedious when T is large. More examples can be found in Shao and Steel^[2] and Shao and Wang.^[3]

Suppose that we can generate B (a large number) data sets from the postulated model. Then, we may replace the derivations in the traditional approach by empirical estimates based on the B data sets. For example, instead of using the theoretical formula for the variance of an estimator, we can calculate the same estimator repeatedly B times and use the sample variance based on the resulting B estimates. We may call this the simulation approach.

In practice, however, generating multiple data sets is impossible because the postulated model usually involves unknown quantities. What we can do is to substitute unknown quantities in the postulated model by some estimates (based on the original data) and then apply the simulation approach. This combination of substitution and simulation is exactly the *bootstrap* method proposed by Efron,^[4] which replaces complicated theoretical derivations

by repeatedly generating data and computing estimates. (In “Generating Bootstrap Data” and “Using Bootstrap Data,” we shall illustrate how to use the bootstrap in the previously discussed poverty line problem.) Because of the availability of high-speed computers, the bootstrap has become very popular and attractive to researchers in recent years.

There are three key issues in applying the bootstrap method. First, we need to know how the bootstrap data sets are generated. Second, we need to choose a procedure of using the bootstrap data in inference. Finally, we need to establish the validity of the bootstrap, although the work required in establishing the validity of the bootstrap is different from the derivations required by the traditional approach.

GENERATING BOOTSTRAP DATA

In general, bootstrap data should be generated by mimicking the process of generating the original data.

Parametric Bootstrap

Suppose that the original data are from a parametric population $P\theta$, where θ is a vector of unknown parameters. If $\hat{\theta}$ is the chosen estimator of θ based on the original data, then bootstrap data should be generated from $P_{\hat{\theta}}$. For example, if $X_1, \dots, X_n$ are iid with a density of

$$\frac{1}{\sigma} f\left(\frac{x - \mu}{\sigma}\right)$$

where μ and $\sigma > 0$ are unknown parameters and f is a known density, then the bootstrap data may be generated from the density

$$\frac{1}{\hat{\sigma}} f\left(\frac{x - \hat{\mu}}{\hat{\sigma}}\right)$$

where $\hat{\mu}$ and $\hat{\sigma}$ are estimators of μ and σ , respectively, based on $X_1, \dots, X_n$ (e.g., the maximum likelihood estimators). This is referred to as the parametric bootstrap.

Nonparametric Bootstrap

When the original data $X_1, \dots, X_n$ are iid from a distribution $\hat{F}$ from a nonparametric family, a simple nonparametric bootstrap generates bootstrap data from the empirical distribution $\hat{F}$ (constructed using $X_1, \dots, X_n$), which amounts to generating a simple random sample with replacement from the observed values $X_1, \dots, X_n$.

In the comparison of K treatments, the original data are independently generated from K populations (i.e., $X_{k1}, \dots, X_{kn_k}$ are iid from F_k , $k = 1, \dots, K$). In such a case, a

stratified bootstrap should be applied (i.e., for each k , we generate a simple random sample from $X_{k1}, \dots, X_{kn_k}$, and the bootstrap data are generated independently across k).

Longitudinal Bootstrap

In medical studies, frequently data are longitudinal in the sense that repeated (dependent) measurements are obtained from each sampled subject. The bootstrap data should also have the same or very similar dependence structure. The simplest way is to use the subject as the primary unit in generating bootstrap data. For example, suppose that a 2×2 crossover design is used for comparing two treatments, A and B ; i.e., n subjects are randomly assigned to two groups (of sizes n_1 and n_2) and subjects in group 1 (or group 2) receive two different treatments on the order of A and B (or B and A). Let Y_{kij} be the j th observation from the i th subject in the k th group. Then, each subject has a vector of two observations $X_{ki} = (Y_{ki1}, Y_{ki2})$. Bootstrap data can be generated by taking a simple random sample with replacement from the vectors $X_{k1}, \dots, X_{kn_k}$, independently across k .

Bootstrapping Linear Models

Suppose that the original data follow a linear model:

$$E(y_i | Z_i) = \beta' Z_i, \quad i = 1, \dots, n \quad (3)$$

where Z_i is the i th value of a covariate, β is a vector of unknown parameters, $E(y|z)$ denotes the conditional expectation of y given z , and y_i is independent. Note that model (1) is a special case of model (3).

If Z_i is a random observation, then a nonparametric bootstrap, which is also referred to as bootstrapping pairs, generates bootstrap data by taking a simple random sample with replacement from the pairs $(y_1, Z_1), \dots, (y_n, Z_n)$. This bootstrap is actually the same as that in “Nonparametric Bootstrap.”

Under model (3), it is often more efficient to apply the following semiparametric bootstrap. Suppose that the regression parameter β in Eq. 3 is estimated by $\hat{\beta}$ (e.g., the least squares estimator). Assume that given Z_i s, $e_i = y_i - \beta' Z_i$, $i = 1, \dots, n$, are iid with a mean of 0 and that:

$$\sum_{i=1}^n \hat{e}_i = 0$$

where $\hat{e}_i = y_i - \hat{\beta}' Z_i$ is the i th residual. Then, a bootstrap sample of e s can be generated by taking a simple random sample with replacement from the residuals $\hat{e}_1, \dots, \hat{e}_n$ and the i th bootstrap y value is obtained by adding $\hat{\beta}' Z_i$ to the i th bootstrap value of e . This bootstrap is commonly referred to as bootstrapping residuals.

Without-Replacement Bootstrap

In sample surveys, the original dataset is often sampled without replacement from a finite population. Consider for simplicity the case where $X_1, \dots, X_n$ is a simple random sample without replacement from a finite population with N units. Ideally, one should generate a bootstrap sample by taking a simple random sample without replacement from $X_1, \dots, X_n$, where the bootstrap sampling fraction is the sample as the original sampling fraction n/N . Such a bootstrap procedure, however, is often impractical. For example, if $n = 100$ and $N = 10,000$, then $n/N = 1\%$ and the bootstrap sample size has to be 1.

The following without-replacement bootstrap method was proposed in Gross^[5] and Chao and Lo.^[6] Assume for simplicity that $N = kn$ with an integer k . We first create a pseudo-population of size N by replicating $X_1, \dots, X_n$ exactly k times and then generate a bootstrap sample by taking a simple random sample of size n without replacement from the pseudo-population. Note that the bootstrap sampling fraction is the same as the original sampling fraction.

Other modified without-replacement bootstrap procedures can be found in Sitter.^[7]

Bootstrapping Imputed Data

Nonresponse often occurs in medical studies and sample surveys. One popular method of handling nonresponse is imputation. Suppose that we have data (X_i, a_i) , $i = 1, \dots, n$, where $a_i = 1$ indicates that X_i is a respondent and $a_i = 0$ indicates that X_i is an imputed value (i.e., the original value of X_i is missing). Usually, the imputation procedure is constructed so that estimators calculated by treating imputed values as observed data and using formulas for the case of no response are still valid (i.e., almost unbiased and consistent). However, applying the bootstrap by treating imputed values as observed data usually produces wrong results.

A bootstrap procedure that takes imputation into account can be described as follows.^[8,9] Suppose that the original data are iid. First, we generate $X_1^*, \dots, X_n^*$ by taking a simple random sample with replacement from $X_1, \dots, X_n$. Let a_i^* be the a value corresponding to X_i^* . If $a_i^* = 1$, we set $\tilde{X}_i^* = X_i^*$. If $a_i^* = 0$, we obtain an imputed $\tilde{X}_i^*$ by using the same imputation procedure for the original dataset. The resulting bootstrap dataset is then $\tilde{X}_1^*, \dots, \tilde{X}_n^*$.

USING BOOTSTRAP DATA

Bootstrap data are usually used in variance estimation and/or construction of confidence sets.

Bootstrap Variance Estimators

Consider the variance estimation problem for a given estimator $\hat{\theta}$. Let X^* be a bootstrap dataset generated

according some procedure (e.g., one of the methods in “Generating Bootstrap Data”). Let X^{*b} , $b = 1, \dots, B$, be iid copies of X^* , and let $\hat{\theta}^{*b}$ be the same as $\hat{\theta}$ but based on the bootstrap dataset X^{*b} . The bootstrap variance estimator for $\hat{\theta}$ is:

$$v_B = \frac{1}{B-1} \sum_{b=1}^B (\hat{\theta}^{*b} - \bar{\theta}^*)^2$$

where $\bar{\theta}^*$ is the average of $\hat{\theta}^{*b}$, $b = 1, \dots, B$.

Consider for example the estimation of poverty line described in the “Introduction.” A bootstrap variance estimator for $\hat{\theta}$ can be obtained by generating bootstrap dataset X^{*b} according to one of the procedures in “Bootstrapping Linear Models” and by computing $\hat{\theta}^{*b}$ by solving Eq. 2 based on X^{*b} , $b = 1, \dots, B$. Although the amount of computation is large, the computation is routine once a program of solving Eq. 2 is available.

Bootstrap Confidence Sets: Percentile Type

Let θ be a real valued parameter of interest. Consider the problem of constructing a confidence bound or interval for θ . Efron^[10] provided the following bootstrap percentile method. Let $\hat{\theta}^{*b}$ be defined as in “Bootstrap Variance Estimators” and let $\hat{\theta}^*(\alpha)$ be the “sample” 100 α th percentile of $\hat{\theta}^{*b}$, $b = 1, \dots, B$. Then, a $1 - \alpha$ upper (or power) confidence bound for θ is $\hat{\theta}^*(1 - \alpha)$ (or $\hat{\theta}^*(\alpha)$) and a $1 - 2\alpha$ confidence interval for θ is $[\hat{\theta}^*(\alpha), \hat{\theta}^*(1 - \alpha)]$.

To improve the bootstrap percentile confidence bounds and intervals, Efron^[10] proposed the bootstrap bias-corrected percentile confidence bounds and intervals. The bootstrap bias-corrected percentile lower confidence bound is $\hat{\theta}^*(\beta)$, where $\beta = \Phi(\Phi^{-1}(\alpha) + 2z_0)$, Φ is the standard normal distribution function, $z_0 = \Phi^{-1}(c/B)$, and c is the number of $\hat{\theta}^{*b}$ values that are less or equal to $\hat{\theta}$. Note that $z_0 = 0$ (i.e., the bias-corrected percentile method is the same as the percentile method) if $\hat{\theta}$ is the median of the bootstrap estimators $\hat{\theta}^{*b}$, $b = 1, \dots, B$.

Efron^[11] proposed a bootstrap accelerated bias-corrected percentile method that further improves the bootstrap bias-corrected percentile method. However, applications of the bootstrap accelerated bias-corrected percentile method involve some derivations that may be complicated.

Bootstrap Confidence Sets: t-Type

Confidence sets for θ are often constructed using the distribution of $\sqrt{n}(\hat{\theta} - \theta)$ or $\sqrt{n}(\hat{\theta} - \theta)/\hat{\sigma}$ where $\hat{\sigma}^2$ is an estimator of the asymptotic variance of $\sqrt{n}(\hat{\theta} - \theta)$. If the 100(1 - α)th percentile of the distribution of $\sqrt{n}(\hat{\theta} - \theta)$ is known and denoted by $z_{1-\alpha}$, then a $1 - \alpha$ lower confidence bound for θ is:

$$\hat{\theta} - n^{-1/2} z_{1-\alpha}$$

If the $100(1 - \alpha)$ th percentile of the distribution of $\sqrt{n}(\hat{\theta} - \theta)/\hat{\sigma}$ is known and denoted by $t_{1-\alpha}$, then a $1 - \alpha$ lower confidence bound for θ is:

$$\hat{\theta} - n^{-1/2} \hat{\sigma} t_{1-\alpha}$$

However, $z_{1-\alpha}$ and $t_{1-\alpha}$ are typically unknown.

If we approximate the distribution of $\sqrt{n}(\hat{\theta} - \theta)$ by the empirical distribution based on the bootstrap estimators $\sqrt{n}(\hat{\theta}^{*b} - \hat{\theta})/\hat{\sigma}^{*b}$, $b = 1, \dots, B$, then $z_{1-\alpha}$ can be estimated by $z_{1-\alpha}^*$, the 100α th sample percentile of $\sqrt{n}(\hat{\theta}^{*b} - \hat{\theta})/\hat{\sigma}^{*b}$, $b = 1, \dots, B$ and the resulting $1 - \alpha$ bootstrap lower confidence bound for θ is:

$$\hat{\theta} - n^{-1/2} \hat{\sigma} z_{1-\alpha}^* \quad (4)$$

If we approximate the distribution of $\sqrt{n}(\hat{\theta} - \theta)/\hat{\sigma}$ by the empirical distribution based on the bootstrap estimators $\sqrt{n}(\hat{\theta}^{*b} - \hat{\theta})/\hat{\sigma}^{*b}$, $b = 1, \dots, B$, then $t_{1-\alpha}$ can be estimated by $t_{1-\alpha}^*$, the 100α th sample percentile of $\sqrt{n}(\hat{\theta}^{*b} - \hat{\theta})/\hat{\sigma}^{*b}$, $b = 1, \dots, B$, and the resulting $1 - \alpha$ bootstrap lower confidence bound for θ is:

$$\hat{\theta} - n^{-1/2} \hat{\sigma} t_{1-\alpha}^* \quad (5)$$

Bootstrap upper confidence bounds and intervals can be similarly obtained.

The bound in Eq. 4 is referred to as the hybrid bootstrap confidence bound and the bound in Eq. 5 is referred to as the bootstrap- t confidence bound. Although the bootstrap- t method is generally better than the hybrid bootstrap method, the bootstrap- t method requires a consistent estimator $\hat{\sigma}$ that can be easily computed.

VALIDITY OF THE BOOTSTRAP

The following are some cases where the validity of the bootstrap has been established in the literature:

1. The parametric bootstrap. In a parametric problem, the parametric bootstrap ("Parametric Bootstrap") is usually valid. Consider the example in ("Parametric Bootstrap" with $\mu = E(X_1)$, $\sigma^2 = \text{Var}(X_1)$, $\hat{\mu} = \bar{X}$ (the sample mean), and $\hat{\sigma}^2 =$ the sample variance. Then, the bootstrap- t confidence bound

$$\bar{X} - n^{-1/2} \hat{\sigma} t_{1-\alpha}^*$$

is an exact $1 - \alpha$ confidence bound for μ (i.e., the probability that μ is larger than this bound is exactly $1 - \alpha$, regardless of the values of the unknown parameter).

2. Nonparametric bootstrap (stratified or longitudinal) for functions of sample means. When the

nonparametric bootstrap ("Nonparametric Bootstrap" and "Longitudinal Bootstrap") is considered, the bootstrap is asymptotically valid when the estimator $\hat{\theta}$ is a smooth function of (several) sample means. Thus in the estimation of poverty line ("Introduction"), the bootstrap is asymptotically valid if bootstrapping pairs ("Bootstrapping Linear Models") are used.

3. Bootstrapping residuals in linear models. For bootstrapping residuals under the linear model (3) ("Bootstrapping Linear Models"), the bootstrap is asymptotically valid when the estimator is a smooth function of the least squares estimator of β .
4. Bootstrapping imputed data. For bootstrapping imputed data ("Bootstrapping Imputed Data"), the bootstrap is asymptotically valid when the estimator is a smooth function of sample means.

Other theoretical results can be found in Hall^[12] and Shao and Tu.^[13]

A theoretical study is needed to show the validity of the bootstrap in situations where no theoretical confirmation has been made. The theoretical work required in establishing the validity of the bootstrap is typically different from the theoretical derivations required by the traditional approach. For example, in the estimation of poverty line ("Introduction"), for the validity of the bootstrap we only need to show that $\hat{\theta}$ is a differentiable function of sample means based on $X_i = (z_i, y_i, \log z_i, \log y_i, x_{i1}, \dots, x_{iT})$, $i = 1, \dots, n$. The exact forms of the partial derivatives of this perhaps very complicated function are not needed in applying the bootstrap, whereas they have to be explicitly derived if the traditional approach (Taylor's expansion method) is applied.

However, establishing the theoretical validity of the bootstrap is sometimes a difficult research problem (e.g., Refs. [12,13]).

There are many results showing that the bootstrap is better than some traditional or nonbootstrap methods such as the normal approximation.^[12] However, whether the bootstrap is better depends on which method the bootstrap is compared to. In setting confidence bounds, for example, the bootstrap- t confidence bounds are shown to be asymptotically more accurate than the confidence bounds obtained by using normal approximation, but are asymptotically equivalent to the confidence bounds obtained by using the one-term Edgeworth or the Cornish-Fisher expansion.^[12] Thus the reason why the bootstrap is used is not because "the bootstrap is better," but because the bootstrap can replace the complicated derivation of the Edgeworth or the Cornish-Fisher expansion by repeated computations.

APPLICATIONS IN BIOEQUIVALENCE TESTING

In vivo bioequivalence testing based on pharmacokinetic responses (such as area under the blood or plasma

concentration–time curve) is considered as a surrogate for a clinical evaluation of the therapeutic equivalence between two drug products, a test drug (T) and a reference drug (R) (e.g., R is a brand name drug and T is a generic copy). In its 1997 draft guidance,^[14] the U.S. Food and Drug Administration (FDA) started to consider the population bioequivalence (PBE) and the individual bioequivalence (IBE). The PBE addresses drug prescribability, which is referred to as the choice for prescribing an appropriate drug for a physician's new patients among the drug products available, while the IBE refers to drug switchability, which is related to the switch from a drug product to an alternative drug product within the same patient. In assessing the PBE and the IBE, the key statistical issue is to set a confidence bound for a function of population means and variance components.

We focus on the IBE. The study design is the following 2×4 crossover design. n subjects are randomly assigned to two sequences (groups) of sizes n_1 and n_2 . In the first sequence, subjects receive treatments T and R at four periods on the order of TRTR, while in the second sequence, subjects receive treatments at four periods on the order of RTRT. Let y_{ijk} be the observed response (or log response) of the i th subject in the k th sequence at j th period, where $i = 1, \dots, n_k$, $j = 1, \dots, 4$, $k = 1, 2$. The following statistical model is assumed:

$$y_{ijk} = \mu + F_l + W_{ijk} + S_{ikl} + e_{ijk} \quad (6)$$

where μ is the overall mean; F_l is the fixed effect of the l th formulation ($l = T, R$ and $F_T + F_R = 0$); W_{ijk} s are fixed period, sequence, and interaction effects ($\sum_k W_{ijk} = 0$, where $\bar{W}_{lk}$ is the average of W_{ijk} s with fixed (l, k) , $l = T, R$; S_{ikl} is the random effect of the i th subject in the k th sequence under formulation l ; and (S_{ikT}, S_{ikR}) , $i = 1, \dots, n_k$, $k = 1, 2$, are iid bivariate normal random vectors with a mean of 0 and an unknown covariance matrix:

$$\begin{pmatrix} \sigma_{BT}^2 & \rho\sigma_{BT}\sigma_{BR} \\ \rho\sigma_{BT}\sigma_{BR} & \sigma_{BR}^2 \end{pmatrix}$$

e_{ijk} s are independent random errors distributed as $N(0, \sigma_{wl}^2)$; and S_{ikl} s and e_{ijk} s are mutually independent.

Define

$$\theta = \frac{\delta^2 + \sigma_D^2 + \sigma_{WT}^2 - \sigma_{WR}^2}{\max\{\sigma_0^2, \sigma_{WR}^2\}}$$

where σ_0^2 is a given constant specified by the FDA, $\delta = F_T - F_R$ and $\sigma_D^2 = \sigma_{BT}^2 + \sigma_{BR}^2 - 2\rho\sigma_{BT}\sigma_{BR}$ is the variance of $S_{ikT} - S_{ikR}$, which is referred to as the variance because of the subject-by-formulation interaction. According to the FDA,^[14,15] two drug formulations can be claimed to be bioequivalent if the hypothesis:

$$H_0 : \theta \geq \theta_0$$

is rejected at the 5% significance level, where θ_0 is a given constant specified by the FDA.

In the FDA,^[14] the bootstrap method is proposed for setting a 95% upper confidence bound $\hat{\theta}_U$ for θ so that we reject H_0 if $\hat{\theta}_U < \theta_0$.

Let $\hat{\delta}$, $\hat{\sigma}_{Bl}^2$ and $\hat{\sigma}_{wl}^2$, $l = T, R$, be estimators of δ , σ_{Bl}^2 , and σ_{wl}^2 , $l = T, R$, respectively. If these estimators are obtained using the restricted maximum likelihood method, then the parametric bootstrap in “Parametric Bootstrap” can be applied to generate bootstrap data. If these estimators are obtained using the method of moments, then the longitudinal nonparametric bootstrap method in “Longitudinal Bootstrap” can be applied to generate bootstrap data.

In the FDA,^[14] the bootstrap percentile method (“Bootstrap Confidence Sets: Percentile Type”) is recommended without any indication of why it is recommended. Since 1997, theoretical and empirical research on the validity of the bootstrap confidence bounds has been carried out.^[16,17] In particular, Shao et al.^[17] showed that the bootstrap method produces asymptotically valid results. For example, when $\hat{\delta}$, $\hat{\sigma}_{Bl}^2$, and $\hat{\sigma}_{wl}^2$ are moment estimators, they are smooth functions of some sample means, in which case the asymptotic validity of the bootstrap has been established (“Validity of the Bootstrap”).

On the other hand, some nonbootstrap methods in assessing IBE have been found.^[18,19] Because the required theoretical derivation is done in Hyslop et al.,^[19] replacing derivations by computations is no longer necessary and thus it is natural for the FDA^[15] to adopt the method of Hyslop et al. (the nonbootstrap approach) for assessing the IBE in its 2001 guidance. This does not mean that the bootstrap is worse than the method of Hyslop et al. When properly used, the bootstrap should be as accurate as, or even better, than the Hyslop et al. method.

Unfortunately, the FDA incorrectly applied the Hyslop et al. method to the PBE problem. One of the key assumption in using the Hyslop et al. method is the independence of the estimated variance components, which is true in the IBE problem but not true in the PBE problem (details can be found in Ref. [20]). On the other hand, the application of the bootstrap does not require this assumption. This shows another advantage of using the bootstrap over a nonbootstrap method that requires theoretical formulas. Note that theoretical formulas are frequently derived under some assumptions that vary from problem to problem. If one does not carefully check these assumptions, one may incorrectly use some formulas. The bootstrap, however, is frequently insensitive to the violation of assumptions because the bootstrap does not directly use these theoretical formulas. Of course, the bootstrap may also be misused. But the example of IBE and PBE shows that using the bootstrap may avoid the kind of mistake made by the FDA.

Botanical Drug Product Development: Scientific Issues

Annpey Pong

Merck Research Laboratories, Rahway, New Jersey, U.S.A.

Shein-Chung Chow

Duke University School of Medicine, Durham, North Carolina, U.S.A.

Abstract

A botanical drug product is often recognized as a traditional Chinese (herbal) medicine (TCM). The use of TCM in humans for treating various diseases has a history of a few thousand years, although not much convincing scientific evidence (documentations) regarding clinical safety and efficacy are available. Thus, how to effectively and scientifically develop a promising TCM the Western way has become an important issue in public health. The purpose of this entry is to provide an overview of scientific and/or regulatory issues that are commonly encountered in botanical drug product or TCM development. These issues include, but are not limited to, intellectual property (IP), variation (or consistency) in raw materials, component-to-component interactions, animal studies, matching placebo and calibration of study endpoints in clinical trials, packaging insert, and transition from experience-base to evidence-base clinical practice.

Keywords: Traditional Chinese herbal medicine; Dynamic balance or harmony; Utilization ratio of the extracts (URE); Experience-base clinical practice; Matching placebo.

INTRODUCTION

In recent years, as more and more innovative drug products are going off patents, the search for new or alternative medicines such as botanical drug products that can treat critical and/or life-threatening diseases has become the center of attention of many pharmaceutical companies and research organizations such as the United States National Institutes of Health (NIH). Botanical drug products are often referred to as traditional Chinese herbal medicine (TCM). This leads to the development of TCM, especially for those intended for treating critical and/or life-threatening diseases such as cancer. The use of TCM in humans for treating various diseases has a history of a few thousand years, although not much convincing scientific evidence (documentations) regarding clinical safety and efficacy are available. Thus, how to effectively and scientifically develop a promising TCM the Western way has become an important issue in public health.

A Western medicine (WM) (e.g., a small molecular chemical drug product) often contains a single active ingredient, while a TCM (e.g., a botanical drug product) usually consists of *multiple* active and inactive components. These multiple active and inactive components may not be characterized and their relationships are usually unknown. Thus, in practice, it is of great concern that whether a TCM can be scientifically evaluated the Western way due to some fundamental differences between a WM and a TCM.

The purposes of this entry are: (i) provide a comparison between a WM and a traditional TCM in terms of the fundamental differences; (ii) provide an overview of regulatory requirements for botanical drug product development based on a guidance published in 2004,^[1] (iii) discuss critical scientific and/or regulatory issues that are commonly encountered during the development of a botanical drug product or TCM.

FUNDAMENTAL DIFFERENCES

The process for pharmaceutical/clinical research and development of a chemical drug product or WM is well established, and yet it is a lengthy and costly process.^[2] This lengthy and costly process is necessary to ensure the efficacy, safety, quality, stability and reproducibility of the drug product under investigation. For the development of a botanical drug product (or TCM), one may consider directly applying this well-established process. However, this process may not be feasible due to some fundamental differences.^[3] These fundamental differences are summarized in [Table 1](#), and briefly described below.

Medical Theory and Mechanism

TCM has a long history of holistic medical system encircling the entire scope of human experience. It combines the

Table 1 Fundamental Differences between a WM and a TCM

Description	Western Medicine	Traditional Chinese Herbal Medicine
Active ingredient	Single	Multiple
Dose	Fixed	Flexible
Diagnostic procedure	Objective; validated	Subjective; not validated
Therapeutic index	Well-established	Not well-established
Medical mechanism	Specific organs	Global dynamic balance/harmony among organs
Medical perception	Evidence-base	Experience-base
Statistics	Population	Individual

use of Chinese herbal medicines, acupuncture, massage, and therapeutic exercises such as *Qi-gong* (the practice of internal *air*) and *Tai-gie* for both treatment and prevention of disease.

The elements of TCM can also help to describe the etiology of disease including six exogenous factors (i.e., wind, cold, summer, dampness, dryness, and fire), seven emotional factors (i.e., anger, joy, worry, grief, anxiety, fear, and fright), and other pathogenic factors. Once all of the information are collected and processed into a logical and workable diagnosis, the traditional Chinese medical doctor can determine the treatment approach.

Under the medical theory and mechanism described above, Chinese doctors believe that all of the organs within a healthy subject should reach the so-called *global dynamic balance or harmony* among organs. An experienced Chinese doctor usually assesses the causes of global imbalance before a TCM with flexible doses is prescribed to fix the problem. This approach is sometimes referred to as a personalized (or individualized) medicine approach.

Medical Practice

Different medical perceptions regarding signs and symptoms of certain diseases could lead to a different diagnosis and treatment for the diseases under study. For example, the signs and symptoms of type 2 diabetic subjects could be classified as the disease of *thirsty reduction* by Chinese doctors. The disease of type 2 diabetes is not recognized by Chinese medical literature although they have the same signs and symptoms as the well-known disease of thirsty reduction. This difference in medical perception and practice has an impact on the diagnosis and treatment of the disease.

In addition, therapeutic effect of WMs is usually sooner than TCMs. TCMs are often considered for patients who have chronic diseases or non-life-threatening diseases. For critical and/or life-threatening diseases such as cancer or stroke, TCMs are often used as the second line or third line treatment with no other alternative treatments. In many cases such as patients with later phase of cancer, TCMs are often used in conjunction with WMs without the knowledge of the primary care physicians.

Techniques of Diagnosis

The Chinese diagnostic procedure for patients with certain diseases consists of four major techniques, namely, inspection, auscultation and olfaction, interrogation, and pulse taking and palpation. All these diagnostic techniques aim mainly at providing an objective basis for differentiation of syndromes by collecting symptoms and signs from the patient.

The Chinese diagnostic procedure is subjective, with large between rater variability. This subjectivity and variability will have an impact not only on the patient’s evaluability but also the prescribability of TCM. For evaluation of a WM, objective criteria based on some well-established clinical study endpoints are usually considered.

In clinical trials, evaluation is usually based on some validated tools such as laboratory tests. Test results are then evaluated against some normal ranges for abnormality. Thus, it is suggested that the Chinese diagnostic procedure must be validated in terms of validity and reliability before it can be used for evaluation of clinical efficacy and safety of the TCM under investigation.

Treatment

TCM prescriptions typically consist of a combination of several components. The combination is usually determined based on the medical theory of global dynamic balance (or harmony) among organs, and the observations from the Chinese diagnostic procedure. The dose and treatment duration are usually flexible. This concept leads to the concept of so-called personalized (or individualized) medicine, which minimizes intra-subject variability. Most WMs contain a single active ingredient. After drug discovery, an appropriate formulation is necessarily developed so that the drug can be delivered to the site action in an efficient way. At the same time, an assay is necessarily developed to quantitate the potency of the drug. The drug is then tested on animals for toxicity, and humans for pharmacological activities. Unlike the WMs, TCMs usually consist of multiple components with certain relative proportions among the components. As a result, the typical

approach for evaluation of single active ingredient for WM is not applicable.

In practice, one may suggest evaluating the TCM component by component. However, this is not feasible due to the following difficulties. First, in practice, analytical methods for quantitation of individual components are often not tractable. Thus, the pharmacological activities of these components are not known. In practice, it is not known which relative proportions among these components can lead to the optimal therapeutic effect of the TCM. In addition, the relative component-to-component and/or component by food interactions are usually unknown, which may have an impact on the evaluation of clinical efficacy and safety of the TCM.

Fixed Dose versus Flexible Dose

Most WMs are usually administered in a fixed dose. On the other hand, a TCM is often prescribed as an individualized flexible dose.

The approach of WM with a fixed dose is a population approach to minimize the between subject (or inter-subject) variability, while the approach to TCM with an individualized flexible dose is to minimize the variability within each individual. In practice, it is a concern whether an individual flexible dose is compatible with a Western evaluation of the TCM. An individualized flexible dose depends heavily upon the subjective judgment, which may vary from one doctor to another. As a result, although an individualized flexible dose does minimize intra-subject variability, the variability from one doctor to another could be huge, and hence non-negligible.

REGULATORY REQUIREMENTS

In 2004, the United States (US) Food and Drug Administration (FDA) published a guidance on botanical drug products, which explains when a botanical drug may be marketed under an over-the-counter drug monograph, when an FDA regulations require approval for marketing of New Drug Application (NDA), and when Investigational New Drug Applications (INDs) for botanical products currently lawfully marketed as foods in US.^[1] In addition, the CDER of FDA also published Manual of Policies and Procedures (MAPP): Review of Botanical Drug Products, which describes the review process in CDER for INDs and NDAs for botanical drug products.^[4] The 2004 MAPP recommends that the guidance entitled *Guidance for Industry – INDs for Phase 2 and Phase 3 Studies, Chemistry, Manufacturing, and Controls Information* be consulted for preparing chemistry, manufacturing, and control (CMC) information that would be submitted for phase 2 and phase 3 studies required for botanical drug product development conducted under INDs in US.^[5]

In FDA guidance 2003, the INDs for botanical drug products should include protocols, CMC, pharmacological and toxicology information, and previous human experience with the product (see Table 2). Requirements for CMC and non-clinical safety assessment are given in Table 3 and Table 4, respectively. Note that CMC requires animal safety test which referred to an acute animal toxicity test applied only to injectable drug product. For matching placebo, the FDA requires that the components of any placebo used must be described. For phase 3 clinical studies, the FDA requires that the following information that (i) description of product and documentation of human experience, (ii) chemistry, manufacturing, and controls, (iii) non-clinical safety assessment, (iv) bioavailability and clinical pharmacology, and (v) clinical considerations must be provided.

Current Review Process for Botanical Products

Regulatory review of botanical submission include CMC information review, clinical pharmacology/biopharmaceutics information review, non-clinical pharmacology and toxicology

Regulatory consideration

information review, and medical/statistical information review. For each botanical submission, FDA establishes a botanical review team (BRT) to assist the review divisions for review of the botanical submission. The BTR review covers (i) biology of the medicinal plants-identification, potential misuse of related species, (ii) pharmacology of the botanical product-activity/toxicology in old documents and new tests, (iii) prior human experiences with the botanical product-past clinical use and relevance to current setting. The botanical team will perform pharmacognosy review throughout the IND and NDA process and botanical-specific medical review. Although regulatory requirements for botanical products are similar to those for chemical drugs in principle, there are many differences in policy issues, which are summarized below:

Purification and Identification - Botanical drugs are derived from vegetable matter and are usually prepared as complex mixtures. Their chemical constituents are not always well defined. In many cases, the active constituent in a botanical drug is not identified, nor is its biological activity well characterized. A new botanical drug (containing multiple chemical constituents) may qualify as a new chemical entity. Both purification and identification of the active ingredients in botanicals are optional and not required. In the initial stage of clinical studies of a botanical drug, it is generally not necessary to identify the active constituents or other biological markers or to have a chemical identification and assay for a particular constituent or marker. Identification by spectroscopic and/or chromatographic fingerprinting and strength by dry weight (weight minus water or solvents) can be acceptable alternatives.

Test and Control - Because of the complex nature of a typical botanical drug and the lack of knowledge of its active constituent(s), FDA may rely on a combination of tests and controls to ensure the identity, purity, quality, strength, potency, and consistency of botanical drugs. These tests and controls include (i) multiple tests for drug substance and drug product (e.g., spectroscopic and/or chromatographic fingerprints, chemical assay of characteristic markers, and biological assay), (ii) raw material and process controls (e.g., strict quality controls for the botanical raw materials and adequate in-process controls), and (iii) process validation (especially for the drug substance).

Individualized Treatments - Botanical therapies are highly individualized with variations in relative contents of multiple plant ingredients tailored for each patient. A sponsor may not submit a separate IND for every change in composition, if similar patients are being treated for the same indication. Studies can be designed to take into account individualized treatments. Multiple formulations can be included in one IND if they are being studied under a single clinical trial. It is important that the IND provide the rationale for using multiple formulations and the criteria used to assign patients to different treatment regimens.

Toxicity - Many medicinal plants with therapeutical potential are quite toxic. Well-known examples of safety issues concerning botanicals include the nephrotoxicity associated with herbal preparations containing aristolochic acid and the hepatotoxicity associated with comfrey products containing pyrrolizidine alkaloid. Other examples include the cardiovascular and central nervous system effects associated with yohimbe and the hepatotoxicity associated with germander and chapparal. When the potential benefit of an investigational drug outweighs its risk in the intended patient population, clinical trials may be allowed to proceed under an IND.

Prior Human Experience - The Guidance also stipulates that because many botanicals have been used as medicine in alternative medical systems for long time, the prior human experiences may substitute for animal toxicology studies in the preliminary safety evaluation of IND studies. The sponsor is encouraged to provide as much data as possible, and the review team for the botanical drug IND generally will accept all available information for regulatory consideration.

Priority - FDA assigns the same level of priority to botanical drug products as to other drugs with respect to meeting with IND sponsors and NDA applicants. For clinical data to support marketing approval, there should be no difference between botanical and non-botanical drugs. The Guidance also provides two flow charts for: 1) the regulatory approaches for marketing botanical drug products in [Fig. 1](#) (attachment B, FDA 2004), and 2) the information to be provided in an IND for a botanical drug in [Fig. 2](#) (attachment A, FDA, 2004).

SCIENTIFIC ISSUES IN BOTANICAL DRUG (OR TCM) DEVELOPMENT

The critical issues that are often encountered during the development of a botanical drug product (or TCM) are briefly summarized below.

Intellectual Property (IP)

Song (2011) indicated that innovation of TCM can be divided into two categories: one is the *self-innovation* of TCM and the other is innovation based on knowledge and techniques of TCM.^[6] Both innovations have been presented with different questions of IP derived from past events. As Song pointed out, under market economy conditions where private rights are legitimate and interests must be maximized, a proper intellectual property legal system should be established for the protection of the innovation of TCM. However, majority of self-innovation of TCM generally do not seek for protection of IP due to the nature of conservativeness of Chinese people and most importantly lack of confidence in current patent system for IP protection.

Attachment B: Information to be provided in an IND for a botanical drug

Fig. 1 Flow chart for approval pathway of an IND for a botanical drug product

Hsiao (2007) pointed out that in the current patent system, an invention has to satisfy the examiner in many aspects including its novelty, inventive step, industrial applicability and enablement.^[7] An invention has to pass the novelty test before proceeding to other steps. Failure to satisfy the novelty requirement will render the invention non-patentable. In the past several decades, novelty has barred many Chinese herbal medicines from patentability because they are either based on traditional formulas or have the same medicinal use and are already available to the public.

As indicated by the Taiwan Intellectual Property Office (TIPO) Guidelines for Patent Examination, an invention is

referred to as any creation of technical concepts by utilizing the rules of nature. TIPO adopts the standard of absolute novelty in the sense that an invention has to be new and nothing similar to those that have appeared before the date of filing. TIPO has established a database of classics and traditional formulas that are in the public domain. Along this line, there are several possible types of end products of traditional Chinese medicine deriving from traditional knowledge, methods of treatments, products and processes are patentable.^[8] Despite the controversies of patenting traditional medicines, the patenting of products and processes of Chinese herbal inventions is not a novel idea.

Attachment A: Regulatory approaches for marketing botanical drug products

Fig. 2 Flow chart for regulatory approaches for marketing botanical drug products

Variation (Consistency) in Raw Materials

One of the critical issues in TCM manufacturing is variation in raw materials. The variation in raw materials, which may be due to the fact that they come from different regions, climates, and time of harvest, could have a negative impact on the quality of the TCM and consequently

the safety and efficacy of the TCM. Yan and Qu (2013) indicated that the efficacy of a TCM depends upon the combined effects of its components.^[9] Variation in chemical composition between batches of TCM has been always the deterring factor of achieving consistency in efficacy. These components, however, may or may not be correlated and may have component-to-component interaction which

will have an impact on achieving optimal therapeutic effect of the TCM. In practice, unfortunately, the correlations among the components and their relative ratios for achieving optimal therapeutic effect are often unknown.

Yan and Qu (2013) indicated that batch mixing process can significantly reduce the batch-to-batch variation in TCM extracts by mixing them in a *well-designed* proportion, which is referred to as utilization ratio of the extracts (URE).

They proposed a batch mixing optimization model to reduce variation in raw materials and improve quality of the TCM under development. Their method is briefly described below. Suppose that there are t (target) components with controlled contents in the mixture. Let s be the number of storage tanks, i.e., the maximum number of batches of extracts that can be stored. Also let $x = (x_1, x_2, \dots, x_s)$ be the amounts of each stored batch of extract used for mixing and $u = (u_1, u_2, \dots, u_s)$, the amounts of each batch of extract stored. Define $a_k = (a_{1k}, a_{2k}, \dots, a_{tk})'$, the contents of the constituents in the k th batch of extract stored. For unidentified constituents, test values such as peak areas on the chromatographic fingerprint obtained by certain analytical methods can be used. Thus, we have $A = (a_1, a_2, \dots, a_s)$, a $t \times s$ matrix that consists of the contents of the components in the batches of extracts stored. Now, let b be the amount of mixture needed in each batch and (L_i, U_i) be the minimum and maximum content limits of the i th component. Yan and Qu (2013) proposed to maximize

$$\max \sum_{i=1}^s x_i^2, \quad (1)$$

which maximizes the sum of squares of the used amounts of each batch. Therefore, the optimization model in this study is to maximize the value of (1) under the following constraints

$$\sum_{i=1}^s x_i = b, \quad (2)$$

where (2) determines the amount of mixture needed for the follow-up process. The contents of the constituents in the mixture are assumed to be the weighted average of the contents in the extracts, where the weights are the amounts of each batch used for mixing;

$$\min L' \leq \frac{A \cdot x'}{b} \leq \max U', \quad (3)$$

where $\max U = (\max U_1, \max U_2, \dots, \max U_t)$, the maximum content limits for the components in the mixtures and $\min L = (\min L_1, \min L_2, \dots, \min L_t)$, the minimum content limits for the constituents in the mixtures. (3) ensures that the contents are in the range of their limits, and,

$$0 \leq x' \leq u', \quad (4)$$

where (4) is the maximum amount of each batch that can be used for mixing. Note that the above optimization model can be solved by quadratic programming (QP) algorithm. In TCM manufacturing, batch mixing can be conducted with the extracts obtained from previous processes like decoction, concentration, and purification. The extracts created are first stored in the storage tanks. Batch mixing ratios are calculated according to the optimization model and mixtures are created for the follow-up process.

Component-to-Component Interactions

Unlike most Western medicines, TCM often consists of a number of components whose pharmacological activities may or may not be quantitatively characterized. Besides, the relative proportions (ratios) of the components for achieving optimal therapeutic effect are also unknown in addition to possible component-to-component (drug-to-drug) interaction among these components. Thus, the study of determining the relative ratios of components for achieving optimal therapeutic effect has become the key to the success of the TCM development. To study the main effects and interactions of these components, some commonly employed designs are briefly described below.

Full factorial design – A full factorial design is a design that consists of all possible different combinations of one level from each factor. If there are l_k levels for the k th factor X_k , the corresponding full factorial design is called a general $l_1, l_2, \dots, l_K$ factorial design. In practice, a factorial design is expressed in terms of a number of arrays (or runs) that indicate the levels of each factor. For example, for a typical 2^4 factorial design, the arrangement of the arrays is given in the following standard order (see Table 5). The first column of the design matrix consists of successive minus (–) and plus (+) signs, the second column of successive pairs of (–) and (+) signs, the third column of four (–) signs followed by four (+) signs, and so on. In this 2^4 factorial design, there are four factors at two levels, with a total of $N = 2^4 = 16$ runs. The two levels of each factor are conventionally denoted by (+) and (–). A full factorial design provides estimates not only for main effects but also for interactions with maximum precision. The main effects and interaction effects can easily be obtained using a table of contrast coefficients and/or Yate's algorithm.^[10,11]

Fractional factorial design – A fractional factorial design is a design that consists of a fraction of a full factorial experiment. For example, a $\left(\frac{1}{2}\right)^p$ fraction of a 2^K factorial design is called a 2^{K-p} fractional factorial design. For a 2^{4-1} fractional factorial design, the eight observations cannot provide independent estimates for the 16 effects alone (from the full 2^4) but for some confounding effects, such as the sum of a main effect and a three-factor interaction that are confounded with each other. In practice, however, the three-factor or higher-factor interactions are usually negligible (see Table 6). In this case, a fractional factorial

Table 5 A Full 2^4 Factorial Design

Run	Design matrix				Y
	X_1	X_2	X_3	X_4	
1	–	–	–	–	Y_1

6	+	–	+	–	Y_6
7	–	+	+	–	Y_7
8	+	+	+	+	Y_8

design is useful in estimating the main effects. In practice, a fractional factorial design is useful when there are many factors to be studied because it is almost impossible to perform a full factorial design even at two levels.

Central composite design – A central composite design is a full factorial design or a fractional factorial design augmented by a $\pm\alpha$ level at each of the K factors and n central points. The central composite design consists of one center point, eight points on the cube (a 2^3 factorial arrangement), and six star points. It should be noted that a central composite design with $K = 2$, $\alpha = 1$, and $n = 1$ reduces to a 3^2 factorial design (see Table 7). For a full 2^K factorial design, although the design provides independent estimates for the $2^K - 1$ effects, it does not give an estimate of the experimental error unless some runs are repeated. Unlike the full 2^K factorial design, the central composite design provides an estimate

Table 7 Central Composite Design for $K = 3$ and $n = 1$

Run	X_1	X_2	X_3

12	0	α	0
13	0	$-\alpha$	0
14	0	0	α
15	0	0	$-\alpha$

of the experimental error. The experimental error is usually estimated based on n observations at the central point.

Animal Studies

Since TCM often consists of multiple components, it is unquestionable that many components are successful in suppressing different types of diseases in humans. However there does not appear to be any scientific documentations, which meets stringent Western criteria for safety and efficacy, to support their use in humans. Thus, in the pharmaceutical development, animal studies such as mice, rats, rabbits, dogs, or monkeys for testing toxicity and evaluation of efficacy are required for regulatory review and approval before they can be used in humans.

However, there are tremendous debates regarding whether animal studies are necessary for the development of TCM, especially for those have been used in for thousands of years. Most Chinese doctors suggest that it would be better to focus on clinical development, instead of going back to animal studies to obtain evidence for a precise pharmacological profile. It would be better to focus on safety and efficacy by starting with clinical trials. It is also suggested that studies on mechanisms and active ingredients should be conducted after safety and efficacy have been confirmed.

For development of Western medicines, animal studies (models) are often used to screen experimental drugs before they enter human trials. This is animal models can provide pharmaceutical scientists the insight how do the drugs work in the living system and evaluate the toxicity at various doses assuming that animal model is predictive of human model. Although there have been controversial debates over which diseased animal models should

be used to screen new drugs before they can proceed to the clinical trials, there are certain animal models in different therapeutic areas remain good standards for drug screening used in the pharmaceutical industry. One of the concerns is that apparent physiological and genetic differences between human and animals, which clearly indicate that the diseased models are different from the human equivalent.

Matching Placebo in Clinical Trials

In recent years, randomized controlled trials (RCT) have been recognized as the gold standard in clinical trials for evaluation of safety and efficacy of a test compound under investigation. One of the important components in RCTs is blinding. The ultimate goal of clinical trials is to achieve a double-blind design to avoid any possible operational biases due to the knowledge of the treatment assignment. Qi et al. (2008) conducted a comprehensive review on the validity of matching placebo used in blinded clinical trials for Chinese herbal medicine in recent years and related patents^[12]. The review was conducted based on a database called the *Wanfang Database*, which contains a total of 827 Chinese journals of medicine and/or pharmacy, from 1999 to 2005 and 598 full-length articles related to clinical trials utilizing matching placebo. Qi et al. (2008) concluded the review that researchers in Chinese medicine commonly ignored the quality of the matching placebo in comparison to the test drug. This may have led to substantial bias in clinical trials. As a result, Qi et al. urged that quality specifications and evaluation of the matching placebo must be developed and carefully evaluated in order to reduce possible bias in randomized controlled TCM trials.

Fai et al. also pointed out that in many clinical trials of Chinese herbal medicines, it is very difficult to make a quality matching placebo to achieve the purpose of blinding.^[13] Ideally, the characteristics of the test drug and matching placebo should be identical in color, appearance, smell and taste. The quality matching placebo should be identical to the test drug in physical form, sensory perception, packaging, and labeling, and it should have no pharmaceutical activity. For this purpose, Fai et al. developed a placebo capsule to match a herbal medicine in terms of its physical form, chemical nature, appearance, packaging and labeling. Based on the assessment results, the developed placebo capsule assessment results suggested that the placebo was found satisfactory in these aspects. Thus, it concluded that a matching placebo could be created for a RCT involving herbal medicine.

It should be noted that the preparation of matching placebo is extremely important to maintain the integrity of blinding for avoid any possible operational biases that may be introduced due to the knowledge of the treatment assignment. The oral dosage form of capsule is often considered for preparation of matching placebo for clinical

trials involving Chinese herbal medicines as it may remove the strong smell and taste of the herbal medicines. However, one of the major challenges is that patients or clinicians will reveal the treatment assignments if they break the capsules. Thus, standard operating procedures (SOP) for preventing patients and clinicians from breaking the capsules are necessary developed.

Calibration of Study Endpoints

The primary study endpoints for assessment of safety and effectiveness of a TCM are usually assessed by a quantitative instrument or the four diagnostic procedures by experienced Chinese doctors. The assessment by a quantitative instrument has been criticized in many ways. First, it may not capture the true health of status of the patients with diseases under study (e.g., by asking wrong questions). Second, it may not detect the effect of the test treatment under investigation. The assessment based on a quantitative instrument by experienced Chinese doctors is not only subjective, but also lack of validity. Consequently, the reliability of the assessment is a concern, especially when there is evidence of large rater-to-rater variability.

Thus, although the quantitative instrument is developed by the community of Chinese doctors and is considered a gold standard for assessment of safety and effectiveness of the TCM under investigation, it may not be accepted by the Western clinicians not only due to the lack of validity and reliability, but also the interpretation of the assessment. Thus, for modernization or Westernization of TCMs, whether the subjective quantitative instrument can accurately and reliably assess the safety and effectiveness of the TCM is a concern for development of TCM. In practice, it is then suggested that a clinical trial be conducted to calibrate the subjective quantitative assessment against either life events or well-established clinical endpoints that are commonly used in assessment of Western medicines. The clinical trials should consist of two arms: one arm will include subjects with diseases under study diagnosed by the subjective quantitative instrument and the other arm will include subjects diagnosed by Western diagnostic or testing procedures. Each subject post-treatment will be assessed by both Chinese doctors using the quantitative instrument and Western clinicians based on the well-established and widely accepted study endpoints.^[14]

Package Insert

For the research and development of a TCM, before a TCM clinical trial is conducted, the following questions are commonly asked.

1. Will the TCM clinical trial be conducted by Chinese doctors alone, Western clinicians alone, Western clinicians who have some background of Chinese

herbal medicine alone, or both Chinese doctors and Western clinicians?

2. Will traditional Chinese diagnostic and/or trial procedures be used throughout the TCM clinical trial?
3. Upon approval, is the TCM intended for use by Chinese doctors or Western clinicians?

With respect to the first two questions, if the TCM clinical trial is to be conducted by Chinese doctors alone, the following questions arise. First, should the Chinese diagnostic procedure be validated in order to provide an accurate and reliable assessment of the TCM? In addition, it is of interest to determine how an observed difference obtained from the Chinese diagnostic procedure can be translated to the clinical endpoint commonly used in similar WM clinical trials with the same indication. These two questions can be addressed statistically by the calibration and validation of the Chinese diagnostic procedure with respect to some well-established clinical endpoints for evaluation of Western medicines. If the TCM clinical trial is to be conducted by Western clinicians or Western clinicians who have some background of Chinese herbal medicine, the standards and consistency of clinical results as compared to those WM clinical trials are ensured. However, the good characteristics of TCM may be lost during the process of the conduct of the TCM clinical trials. On the other hand, if the TCM clinical trial is to be conducted by both Chinese doctors and Western clinicians, difference in medical practice and/or possible disagreement regarding the diagnosis, treatment, and evaluation are major concerns.

For the third question, if the TCM is intended for use of Chinese doctors but it is conducted by Western clinicians, difference in perception regarding how to prescribe the TCM is of great concern. The preparation of a package insert based on the clinical data could be a major issue, not only to the sponsor but also to regulatory authorities. Similar comments apply to the situation where the TCM is intended for use of Western clinicians, but the trial is conducted by Chinese doctors.

As a result, it is suggested that the intention of use (i.e., labeling for the indication) be clearly evaluated when planning a TCM clinical trial. In other words, the sponsor needs to determine whether the TCM is intended for use of Western clinicians only, Chinese doctors only, or both Western clinicians and Chinese doctors at the planning stage of a TCM clinical trial, for an adequate package insert of the target diseases under study.

Transition from Experience-Base to Evidence-Base Clinical Practice

TCMs have been in practice for thousands of years. Many of the commonly used TCMs were found safe and efficacious. However, evidence of safety and efficacy of these TCM were not documented for scientific evaluation. Unlike evidence-based clinical data, the experience-based

clinical information has been criticized for lacking of scientific validity and reliability for assessment of safety and efficacy of the TCMs. As a result, experience-based clinical information is considered not only subjective, but also biased and misleading.

In practice, how to collect relevant and important clinical data from experience-based clinical practice is then of particular interest to clinical scientists for development of TCMs. Most Chinese doctors resist to (i) collect clinical data that they are not familiar with, and (ii) cooperate with Western doctors to collect further information from their patients due to fundamental differences in culture and clinical theory, perception, and practice. Thus, the transition from experience-based clinical practice to evidence-based clinical practice requires careful communication and planning. This transition is essential for achieving the ultimate goal of modernization and/or Westernization of TCMs.

CONCLUSION

One of the key issues in botanical drug product or TCM development is to clarify the difference between Westernization of TCM and modernization of TCM. For Westernization of TCM, we follow regulatory requirements at critical stages of the process for pharmaceutical development including drug discovery, formulation, laboratory development, animal studies, clinical development, manufacturing process validation and quality control, regulatory submission, review, and process despite the fundamental differences between WM and TCM. For modernization of TCM, it is suggested that regulatory requirements should be modified in order to account for the fundamental differences between WM and TCM. In other words, we still ought to be able to see if TCM is really working with modified regulatory requirements using Western clinical trials as a standard for comparison.

In practice, it is recognized that WMs tend to achieve the therapeutic effect sooner than that of TCMs for critical and/or life-threatening diseases. TCMs are found to be useful for patients with chronic diseases or non-life-threatening diseases. In many cases, TCMs have shown to be effective in reducing toxicities or improving safety profile for patients with critical and/or life-threatening diseases. As a strategy for TCM research and development, it is suggested that (i) TCM be used in conjunction with a well-established WM as a supplement to improve its safety profile and/or enhance therapeutic effect whenever possible, and (ii) TCM should be considered as the second line or third line treatment for patients who fail to respond to the available treatments. However, some sponsors are interested in focusing on the development of TCM as a dietary supplement due to (i) the lack or ambiguity of regulatory requirements, (ii) the lack of understanding of the medical theory/mechanism of TCM, (iii) the confidentiality

of non-disclosure of the multiple components, and (iv) the lack of understanding of pharmacological activities of the multiple components of TCM.

Since TCM consists of multiple components which may be manufactured from different sites or locations, the post-approval consistency in quality of the final product is both a challenge to the sponsor and a concern to the regulatory authority. As a result, some post-approval tests, such as tests for content uniformity, weight variation, and/or dissolution and (manufacturing) process validation, must be performed for quality assurance before the approved TCM can be released for use.

A comprehensive summarization of the issues in botanical drug product development can be found in Chow (2015).^[15]

Bracketing Design

John R. Murphy

Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

Abstract

Bracketing is the design of a stability schedule so that at any time point only the samples on the extremes, are tested. This entry provides a brief overview of this concept.

INTRODUCTION

Bracketing is a special term used in stability design. Since the amount of data required to demonstrate the stability characteristics of a product can often be large and expensive to generate, methods to reduce the size of stability studies have been proposed. As defined in the Glossary of the International Conference on Harmonization (ICH) Stability Guideline Q1A,^[1] *bracketing* is: “The design of a stability schedule so that at any time point only the samples on the extremes, for example, of container size and/or dosage strengths, are tested.” The Glossary further explains that the design assumes that the intermediate condition samples are represented by the extremes and that bracketing may be particularly applicable where strengths are related closely in composition, such as same formulation but different tablet sizes or different amounts filled into capsules. For bracketing across containers, the guideline indicates that bracketing designs may be applicable if the composition of the container and the type of closure are the same.

OVERVIEW

The U.S. Food and Drug Administration (FDA) draft stability guidance^[2] provides more detail about when bracketing may be applied without justification and when bracketing must be justified with theory and/or data. The FDA draft guidance provides an example, reproduced

in [Table 1](#), of a bracketing design for a case where there are three strengths made from a common granulation to be packaged in three different sizes of HPDE bottles with different counts: 30 counts, C1; 100 counts, C2; and 200 counts, C3.

The FDA draft guidelines also cautions that if the statistical analysis determines that there is dissimilarity between the extremes, the intermediate sizes/strengths should be considered to be no more stable than the least stable extreme. This could be a significant drawback to the use of bracketing depending of course, on the particular situation.

It seem clear that bracketing offers the potential for reducing the number of samples in registration stability studies. The question naturally arises whether bracketing has any application in validation studies and marketed product stability studies. For example, would it be possible to bracket across packages in the validation? Even if the all validation lots must be produced, would it be possible to place only some of the package/strength combinations on stability using bracketing? Since bracketing is a relatively new idea for the design of stability studies, these types of questions will continue to surface and will be discussed over the next few years.

CONCLUSION

Bracketing seems to be an idea that many stability studies can utilize to good advantage. However, it is

Table 1 Example of a Bracketing Design

Batch	1									2									3								
	100 mg			200 mg			300 mg			100 mg			200 mg			300 mg			100 mg			200 mg			300 mg		
Strength	C1	C2	C3	C1	C2	C3	C1	C2	C3	C1	C2	C3	C1	C2	C3	C1	C2	C3	C1	C2	C3	C1	C2	C3	C1	C2	C3
Container/ Closure																											
Sample on Stability	X		X				X	X	X	X						X	X	X	X						X		X

also clear that the regulatory agencies worldwide will move forward with some caution, and proposed protocols will need to be cleared almost on a case-by-case basis at first. The ICH Stability Guideline and the FDA Draft Stability Guidance both encourage consultation with the appropriate regulatory body to get agreement about applying bracketing in the stability study before the protocol is executed.

Bridging Studies

Jen-pei Liu

Division of Biometry, Department of Agronomy, and Institute of Epidemiology, National Taiwan University, Taipei, Taiwan; and Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan

Abstract

As globalization becomes the key to survival of pharmaceutical companies, issues concerning the design and the analysis of bridging studies with respect to geotherapeutics pose new challenges to statisticians. This entry addresses some of these challenges and some methods of overcoming them.

INTRODUCTION

For the marketing approval of a pharmaceutical product, sponsors are required to provide substantial evidence of effectiveness and safety from adequate and well-controlled clinical trials. On the other hand, the U.S. Food and Drug Administration (FDA) recommends that usually at least two so-called “pivotal trials” in the same targeted patient population be performed to confirm the reproducibility of evidence on efficacy, safety, and dose response. However, after the pharmaceutical product is approved by the original region such as the United States or European Union, sponsors might seek the registration of the product in the new region. Due to the possible differences on ethnicity and clinical practice of the new region, the concerns that these differences may have an impact on the safety, efficacy, dose, and dosing regimen have limited the willingness for the regulatory authority in the new region, as a whole, to accept the foreign clinical data generated in the original region. Consequently, the regulatory authority in the new region has often requested the replication of all, or much, of the foreign clinical data in the new region. This extensive duplication of clinical evaluation in the new region not only requires valuable development resources but also delays the availability of the new pharmaceutical product to patients in need in the new region. To resolve this dilemma, the International Conference on Harmonization (ICH) has published a tripartite E5 guidance titled “Ethnic Factors in the Acceptability of Foreign Clinical Data” to address the above issues.^[1]

According to the ICH E5 guidance, ethnic factors are factors relating to races or larger populations grouped according to common traits and customs. Ethnic factors may be classified as intrinsic or extrinsic. Intrinsic ethnic factors are factors that help to define and to identify a subpopulation and may influence the ability to extrapolate clinical data between regions. Examples of intrinsic factors include genetic polymorphism, age, gender, height,

weight, lean body mass, body composition, and organ dysfunction. On the other hand, extrinsic ethnic factors are factors associated with the environment and culture in which a person lives. Extrinsic factors tend to be less genetically and more culturally and behaviorally determined. Examples of extrinsic factors include the social and cultural aspects of a region, such as a medical practice, diet, use of tobacco, use of alcohol, exposure to pollution and sunshine, socioeconomic status, and compliance with prescribed medications; particularly important are the reliance on studies from a different region, practices in clinical trial design, and conduct.

The objective of the guidance is to provide a framework for the evaluation of the impact of ethnic factors on the efficacy and the safety of a pharmaceutical product at a particular dosage or dose regimen. In addition, it describes regulatory strategies of minimizing duplication for clinical data and the requirement of bridging evidence for extrapolation of foreign clinical data to a new region. According to the ICH E5 guidance, a bridge data package consists of (i) selected information from the Complete Clinical Data Package (CCDP), which is relevant to the population of the new region; and, (ii) if needed, a bridging study to extrapolate the foreign efficacy and/or safety data to the new region. In other words, bridging evidence is actually provided either in the CCDP generated during the clinical drug development program for submission to the original region, or in a bridging study conducted in the new region after the pharmaceutical product is approved in the original region. If the bridging evidence provided in the CCDP cannot allow the extrapolation of foreign clinical data to a new region, then a bridging study should be conducted in the new region to generate a limited amount of clinical data to bridge the clinical data between the two regions. As a result, the ICH defined a bridging study as a supplemental study performed in the new region to provide pharmacodynamic (PD) or clinical data on efficacy, safety, dosage, and dose regimen in the new region that will

allow the extrapolation of the foreign clinical data to the new region. Bridging studies can also include additional pharmacokinetic (PK) information.

NATURE AND TYPES OF BRIDGING STUDIES

In general, the types of bridging studies required depend upon the ethnic sensitivity of the pharmaceutical agent, experience of the drug class, extrinsic ethnic factors, and ethnic differences between the new and original regions. From the ICH E5 guidance, the following table is a summary of types of bridging studies with respect to the above-mentioned factors:

<i>Medicine</i>	<i>Region</i>	<i>Medical practice</i>	<i>Drug class</i>	<i>Clinical experience</i>	<i>Bridging studies</i>
Insensitive	—	Similar	—	—	No
Sensitive	Similar	—	—	Sufficient	No
Sensitive	Dissimilar	Similar	Familiar	—	PD
Dosage	—	Different	Unfamiliar	Insufficient	CCT ^a

^aControlled clinical trials.

If the populations between the two regions are similar, medical practical practices are also similar, and sufficient experience with the pharmaceutical is available, too, the extrapolation of foreign clinical data to the new region might be allowed without a bridging study even when the medicine is ethnically sensitive. On the other hand, from the above table, if the pharmaceutical is ethnically sensitive and the populations of the two regions are not similar but the medical practice and the conduct of the clinical trials are similar and the drug class is also a familiar one in the new region, then a controlled pharmacodynamic (PD) study with a well-established pharmacological end point may generate the necessary data to bridge the foreign clinical data. However, the uncertainty of the dose used in the new region, insufficient clinical experience, dissimilar medical practice, or unfamiliar drug class may warrant that controlled clinical trials be conducted in the new region to obtain the necessary bridging data. Occasionally, the bridging safety studies might be needed to accurately determine the rates of the relatively common adverse events in the new region and to detect some serious adverse events. However, in general, the relationship among a PK, PK/PD, and clinical bridging studies is not always clear-cut. The translation of similarity observed from PK studies to similarity or reproducibility in clinical trials requires further research. This type of research can start by examining systematically the relationship among PK, PD, and clinical data of the approved drugs by drug class.

As pointed out by the ICH E5 guidance, bridging studies might not be necessary in some situations for the extrapolation of the foreign clinical data to the new region. Chow et al.^[2] proposed a method to evaluate the necessity

of bridging studies that is based on the concept of reproducibility and generalizability of the foreign clinical data. Reproducibility is the probability of reaching the positive treatment effect in the second clinical trial with the same patient population given the result of the positive treatment effect for the first trial. On the other hand, generalizability is the probability of reaching the positive treatment effect in the second clinical trial with the different patient population given the result of the positive treatment effect for the first trial. For the calculation of generalizability, the differences in population mean and variance between the new and original regions are characterized by a sensitivity index. Chow et al.^[2] proposed the following sequential strategy for the necessity of bridging studies:

- Step 1: From the CCDP, summarize the results and calculate the reproducibility probability. If the reproducibility probability is greater than some prespecified level set by the regulatory authority, then stop and suggest that bridging studies, from a statistical viewpoint, are not required for the evaluation of the ability of extrapolation of the foreign clinical data to the new region. Otherwise go to Step 2.
- Step 2: Identify the sensitivity indices.
- Step 3: Compute the generalizability probability. Compare the generalizability with the regulatory requirement to determine the necessity of bridging studies and the types of bridging studies to be conducted in the new region.

The ICH E5 guidance stresses that the regulatory authority in the new region request only additional bridging data necessary to assess the ability to extrapolate the foreign clinical data from the CCDP to the new region. As a result, the ability for extrapolation is the key to the evaluation of bridging data generated in the new region. The ICH E5 describes two situations where the data generated from a bridging study can provide scientific evidence for allowing the extrapolation of the foreign clinical data to the new region:

- Situation 1: If the bridging study shows that dose response, safety, and efficacy in the new region are similar, then the study is readily interpreted as capable of bridging the foreign clinical data.
- Situation 2: If a bridging study indicates that a different dose in the new region results in a safety and efficacy profile that is not too substantially different from that derived in the original region, it will often be possible to extrapolate the foreign clinical data to the new region, with appropriate dose adjustment.

EXTRAPOLATION AND SIMILARITY

Although the ICH E5 guidance clearly states that the assessment of the ability of extrapolation of the foreign data relies on the similarity of dose response, efficacy, and safety between the new and original regions, with or without dose adjustment, it does not provide a precise definition of similarity. Different interpretations of similarity have been proposed.^[3-5] They include positive treatment effect, equivalence, non-inferiority, and consistency.

For simplicity, we only consider the problem for assessment of similarity on efficacy for comparing a test medicine with a placebo control. Similar ideas can be directly applied to the evaluation of similarity with respect to either dose response or safety. Let $\mathcal{Y}_{ijk}$ be the some efficacy response variable for patient k receiving treatment j in region i , $k = 1, \dots, K$; $j = T$ (test), P (placebo); and $i = O$ (original), N (new). For the sake of illustration, we assume that approximately $\mathcal{Y}_{ijk}$ is independently distributed as a normal distribution with mean μ_{ij} and known variance σ^2 . The treatment effect for region i is defined as:

$$\Delta_i = \mu_{iT} - \mu_{iP}, \quad i = O, N$$

The concept of the positive treatment effect is defined as follows. Because the test medicine has already been approved in the original region due to its proven efficacy against placebo control, if the data collected from the bridging studies in the new region demonstrate superior efficacy of the test medicine over placebo control, then the efficacy of the new region is claimed to be similar to that of the original region. In other words, under the concept of the positive treatment, the effect for similarity can be evaluated through the following hypothesis:

$$H_0 : \Delta_N \leq 0 \quad \text{vs.} \quad H_a : \Delta_N > 0 \quad (1)$$

However, the concept of the positive treatment effect does not really assess the similarity of the magnitude of efficacy between the two regions. Therefore Liu et al.^[3] applied the concept of average bioequivalence to the evaluation of similarity for the extrapolation of foreign clinical data. The idea is that the similarity with respect to efficacy should be interpreted as the difference of treatment effects between regions within some clinically acceptable limit, say δ . The relationship between δ and overall treatment effect Δ can be expressed as $\delta = f\Delta$. δ is clinically acceptable and meaningful only if $0 < f < 1$ because similarity dictates that the difference of treatment effects between regions should be smaller than the overall treatment effect. Let $\theta = (\mu_{NT} - \mu_{NP}) - (\mu_{OT} - \mu_{OP})$, then the corresponding hypothesis can be formulated as the following two-sided equivalence hypothesis:

$$H_0 : \theta \leq -\delta \quad \text{or} \quad \theta \geq \delta \quad \text{vs.} \quad H_a : -\delta < \theta < \delta \quad (2)$$

On the other hand, the non-inferiority test may also be appropriate for evaluating the similarity between the two regions because the efficacy of the new region can be claimed to be similar to, if it is not inferior to that of, the original region. The one-sided non-inferiority hypothesis is given as:

$$H_{0L} : \theta \leq -\delta \quad \text{vs.} \quad H_a : \theta \geq -\delta \quad (3)$$

Shih^[5] proposed the idea of the consistency for evaluation of the similarity of the efficacy between the new and original regions. Let $\mathbf{w} = \{w_1, \dots, w_H\}$ be the results of the H reference studies that were conducted in the original region and let v be the result of the bridging study conducted in the new region. The result of the bridging study is said to be consistent with the previous results $\mathbf{w}$ if:

$$p(v|\mathbf{w}) \geq \min \left\{ p(w_h|\mathbf{w}), h = 1, \dots, H \right\} \quad (4)$$

where $p(u|\mathbf{w})$ is the predictive probability function of the study u given the previous result $\mathbf{w}$.

The concept of consistency in Eq. 4 can be reformulated as

$$|\Delta_N - \Delta| < v \quad (5)$$

where Δ is the mean of the treatment effects over the H previous studies. Under the normal assumption, $v^2 = \max \{ (\Delta_h - \Delta)^2, h = 1, \dots, H \}$.

DESIGN AND ANALYSIS

The goal of analysis of the clinical data generated by the local bridging study is not only to provide the information on the dose response, efficacy, and safety with the data in the patient population of the new region alone, but also to evaluate the similarity of dose response, efficacy, and safety with the foreign clinical data by the clinical trials conducted in the original region. As a result, the bridging evidence provided by this strategy consists of the clinical data by the local bridging study as well as those by the clinical trial in the original region, which are not concurrently generated and hence are not internally valid. To minimize the bias on similarity inference, the clinical data by the new and the original regions must be at least externally valid. It follows that the bridging study in the new region should replicate the randomized parallel dose response design as close to those of the original region as possible with respect to study design, inclusion and exclusion criteria, dosage, dosage regimen, and control. The difference between the bridging study and trials conducted in the original region should be limited only to the region and sample size, or possibly end points and duration.

Liu et al.^[3] proposed a hierarchical model to evaluate the similarity in terms of equivalence or non-inferiority on the results between the bridging study and the original region. Under the proposed hierarchical model, the maximum likelihood estimate (MLE) of θ and its asymptotic variance can be obtained to construct a $(1 - 2\alpha)100\%$ confidence interval for y . The similarity of the efficacy provided by the bridging study in the new region and foreign clinical data can be claimed if the $(1 - 2\alpha)100\%$ confidence interval for y is completed within $(-\delta, \delta)$. Similarly, the efficacy of the bridging study in the new region is not inferior to that provided by the foreign clinical data if the lower limit of the $(1 - 2\alpha)100\%$ confidence interval for y is greater than $-\delta$. If the variance is the same for all trials in the original region and the new region, and if treatment allocation is 1:1, for type I and type II error rates controlled at α and β levels, respectively, the total sample size for the bridging study is given as

$$n_N \geq 1 / \left\{ (f/CV)^2 [z(\alpha) + z(\beta)]^2 - (1/N) \right\} \quad (6)$$

where $f = \delta/(\mu_{OT} - \mu_{OP})$, $CV = 2\sigma/(\mu_{OT} - \mu_{OP})$, N is the total number of the patients in CCDP provided by the original region, and σ^2 is the common variance. Under the hierarchical model, the sample size required for bridging studies sometimes is forbiddingly large to practically conduct bridging studies in the new region. In addition, one of the objectives of a bridging study is to minimize an unnecessary duplication of clinical data in the new region. Therefore it is imperative to borrow the strength and to incorporate the information on dose response, efficacy, and safety from the CCDP generated in the original region into the analysis of the data obtained from the bridging study in the new region. Liu et al.^[4] suggest applying the empirical Bayesian method to the assessment of similarity in terms of a positive treatment effect. They proposed the following model:

$$Y = \mu_p(1 - x) + \{\mu_{NT}Z + \mu_{OT}(1 - Z)\}X + \varepsilon \quad (7)$$

where μ_p is the common placebo mean for both new and original regions; $\mu_{NT}(\mu_{OT})$ is the treatment mean for the new (original) region; X , being 1(0), indicates the treatment (placebo) group; and Z , being 1(0), indicates the new (original) region. Given the data collected from the bridging study and prior distribution on $(\mu_p, \mu_{NT}, \mu_{OT})$, similarity on efficacy in terms of a positive treatment effect for the new region can be concluded if the posterior probability:

$$Pr\{\mu_{NT} - \mu_p > 0 | \text{bridging data and prior}\} > 1 - \alpha$$

for some prespecified $\alpha > 0$.

Under further assumption of $\mu_{NT} = \mu_{OT}$, the sample size for the bridging study can be expressed in terms

of the sample size in the CCDP and the strength of the evidence of the positive treatment effect provided by the CCDP in the original region. In addition, this approach assumes the same placebo mean for both new and original regions. It follows that the sample size for the bridging study decreases when the number of patients assigned to the treatment group increases. For establishing similarity using the concept of consistency using normal responses, let w_h be the standardized between-group difference in means ($h = 1, \dots, H$). If the total sample size for each of H reference studies is reasonably large, then w_h approximately follows a normal distribution with common mean Δ and variance 1 ($h = 1, \dots, H$). Under the assumption of vague prior for Δ , the predictive probability function for the standardized between-group difference v for the bridging study follows a normal distribution with mean w and variance $(H + 1)/H$, where w is the mean of $w_1, \dots, w_H$.

Shih^[5] showed that $p(v|w) \geq \min\{p(w_h|w), h = 1, \dots, H\}$ if and only if $(v - w)^2 \leq \lambda = \max\{(w_h - w)^2, h = 1, \dots, H\}$. In addition, let R denote the expanse of all consistent trials $R = \{v: (v - w)^2 \leq \lambda\}$. The cover of this expanse is given by the predictive probability $Pr(R) = 1 - 2\Phi\{-[\lambda H/(H + 1)]^{1/2}\}$, where $\Phi(\cdot)$ denotes the cumulative distribution function of a standard normal distribution. $Pr(R)$ is a probability that quantifies the chance that the results of the bridging study in the new region will be consistent with the experience of the reference studies in the CCDP provided by the original region. If $Pr(R)$ is greater than some prespecified limit set by the regulatory authority, say 90%, Shih^[5] suggests that there is no need to test what has already been shown in the CCDP. Therefore the conventional sample size and power calculation are no longer relevant in this situation. On the other hand, if the reference studies in the CCDP fail to provide sufficient support that $Pr(R)$ meets the regulatory requirement, the bridging study will be the confirmation trial in the new region and hence conventional sample size and power calculation will be required.

Liu et al.^[6,7] proposed a Bayesian approach to evaluation of bridging studies. On the other hand, to avoid the bias due to between-study comparison, the methods in a sequential nature have been proposed to assess bridging studies.^[8,9] Liu et al.^[10] suggest the concept of ICH E5 can be also applied to evaluation of acceptability of foreign bioequivalence data for generic drugs. Most importantly, in September 2006, ICH issued a guidance on the Ethnic Factors in the Acceptability of Foreign Data—Questions and Answers.^[11]

CONCLUSION

The ICH E5 guidance provides the regulatory requirements that the acceptability of foreign clinical data should be evaluated based on the similarity on dose response, efficacy, and safety between the new and original regions. However, it does not provide a precise definition of

similarity. Although various interpretations of similarity have been suggested, no consensus has been reached. Until a scientifically sound and statistically valid definition of similarity is defined, all currently proposed statistical methodology on the bridging studies cannot be installed as the regulatory implementation for the evaluation of extrapolation of the foreign clinical data to the new region. As globalization becomes the key to survival of pharmaceutical companies, issues concerning the design and the analysis of bridging studies with respect to geotherapeutics pose new challenges to statisticians. These issues include the designs of global clinical trials versus multinational bridging study, frequentist approach versus Bayesian approach, use of genomic information, selection of end points for the bridging study, determination of equivalence limits, and sample size requirements. Details regarding the resolutions and/or discussions of these issues can be found in Liu, Chow and Hsiao (2012).^[12]

Abstract

After the test product has been approved for commercial marketing in the original region based on its proven efficacy and safety, and if the sponsor wants to apply the new drug registration to a new region, a bridging study may be conducted in the new region to provide pharmacodynamic or clinical data on efficacy, safety, dosage and dose regimen to allow extrapolation of the foreign clinical data to the population of the new region. In this entry, we reviewed some statistical methods for bridging studies. In the first part, we reviewed the strategy for determining whether a bridging study is needed for providing substantial evidence in the new region based on the clinical results observed in the original region. In the last three part, we reviewed three statistical methods for assessing the similarity between a bridging study conducted in a new region and studies conducted in the original region.

Keywords: Bridging study; Complete clinical data package (CCDP); Similarity.

INTRODUCTION

The idea of bridging study came from the ICH E5 (1) entitled “Ethnic Factors in the Acceptability of Foreign Clinical Data.” The purpose of the ICH E5 is to facilitate the registration of medicines among ICH regions including European Union (EU), the United States of America (USA), and Japan by recommending a framework for evaluating the impact of ethnic factors on a medicine’s effect such as its efficacy and safety at a particular dosage and dose regimen. By ICH E5, bridging study is defined as a supplementary study conducted in the new region (e.g., Asian Pacific Region) to provide pharmacodynamic or clinical data on efficacy, safety, dosage and dose regimen to allow extrapolation of the foreign clinical data (e.g., data from EU or USA) to the population of the new region. Therefore, a bridging study is usually conducted in the new region only after the test product has been approved for commercial marketing in the original region (e.g., the United States of America or European Union) based on its proven efficacy and safety. Although use of bridging studies for bringing an approved drug product from the original region to a new region has attracted sponsors as well as regulatory authorities in recent years, the key issue however lies on how the ethnic factors influence clinical outcomes for evaluation of efficacy and safety.

The ICH E5 guideline provides regulatory strategies of minimizing duplication of clinical data and requirement of bridging evidence for extrapolation of foreign clinical data to a new region. To do so, the bridging data package should

include (1) information including PK data and any preliminary PD and dose-response data from the complete clinical data package (CCDP) that is relevant to the population of the new region and if needed, (2) bridging study to extrapolate the foreign efficacy data and/or safety data to the new region. If the study medicines are insensitive to ethnic factors, the type of bridging studies (if needed) will depend upon experience with the drug class and upon the likelihood that extrinsic ethnic factors could affect the medicine’s safety, efficacy, and dose-response. On the other hand, for medicines that are ethnically sensitive, bridging study is usually needed since the populations in two regions are different.

The ICH E5 guideline points out that evaluation of the ability of extrapolation of the foreign clinical data relies upon the similarity of dose response, efficacy, and safety between the new and original regions either with or without dose adjustment. Several statistical procedures have been proposed to assess the similarity based on the additional information from the bridging study and the foreign clinical data in the CCDP. In this entry, we will review some statistical methods for bridging studies.

REPRODUCIBILITY AND GENERALIZABILITY

Shao and Chow (2) proposed the concepts of reproducibility and generalizability probabilities for assessment of bridging studies. For convention, we focus on the trials for comparing a test product and a placebo control. Let n_t and

n_p represent the numbers of patients recruited for the test product and the placebo respectively in new region. Let X_i and Y_j be the efficacy responses for patients i and j receiving the test product and the placebo control respectively, $i = 1, \dots, n_T, j = 1, \dots, n_p$. We assume that both X_i 's and Y_j 's are normally distributed with variance σ^2 . Let μ_{NT} and μ_{NP} be the population means of the test and placebo, respectively, and let $\Delta_N = \mu_{NT} - \mu_{NP}$. Subsequently, the hypothesis of testing for the treatment effect is given as

$$H_0 : \Delta_N = 0 \text{ vs. } H_A : \Delta_N \neq 0. \quad (1)$$

The test statistic for (1) under H_0 is taken as

$$T_N = \frac{\bar{x}_T - \bar{y}_p}{\sqrt{\frac{(n_T - 1)s_T^2 + (n_p - 1)s_p^2}{(n - 2)} \left(\frac{1}{n_T} + \frac{1}{n_p} \right)}} \sim t_{n-2},$$

where $\bar{x}_T = \sum_{i=1}^{n_T} x_i / n_T$, $\bar{y}_p = \sum_{j=1}^{n_p} y_j / n_p$, s_T^2 and s_p^2 are the sample variances based on the data from the test and placebo groups respectively, and t_{n-2} represents the t distribution with degrees of freedom $n - 2$ with $n = n_T + n_p$. More specifically, we reject H_0 at the α level of significance if and only if $|T_N| > t_{n-2, 1-\alpha/2}$, where $t_{n-2, 1-\alpha/2}$ is 100(1 - $\alpha/2$)% percentile of the t -distribution with $n - 2$ degrees of freedom. Consequently, the power of T_N is given by

$$p(\theta) = P\left(|T_N| > t_{n-2, 1-\alpha/2} \mid \theta\right) = 1 - \mathfrak{I}_{n-2}\left(t_{n-2, 1-\alpha/2} \mid \theta\right) + \mathfrak{I}_{n-2}\left(-t_{n-2, 1-\alpha/2} \mid \theta\right), \quad (2)$$

where

$$\theta = \frac{\Delta_N}{\sigma \sqrt{\frac{1}{n_T} + \frac{1}{n_p}}}$$

and $\mathfrak{I}_{n-2}(\cdot \mid \theta)$ denotes the cumulative distribution function of the non-central t distribution with $n - 2$ degrees of freedom and the non-centrality parameter θ .

Let T_O represent the test statistics obtained from the original region and t_O the value of T_O based on the data observed from the original region. When the ethnic difference is negligible, we can replace θ in Eq. (2) by its estimate t_O and derive the estimated power

$$\hat{p} = 1 - \mathfrak{I}_{n-2}\left(t_{n-2, 1-\alpha/2} \mid t_O\right) + \mathfrak{I}_{n-2}\left(-t_{n-2, 1-\alpha/2} \mid t_O\right)$$

which consequently can be defined as a reproducibility probability for a future clinical trial with the same patient population. When the ethnic difference is notable, Shao and Chow (2) recommend to calculate the estimated reproducibility probability based on a set of values of θ . If all the estimated reproducibility probabilities obtained based on this set of values of θ meets regulatory requirement,

then the sponsor may stop and conclude that clinical bridging studies are not needed and clinical data in the original region is capable of bridging to the new region. Conversely, if the estimated reproducibility probabilities fail to meet regulatory requirement, then the sponsor may need to prepare for a bridging study.

TEST FOR CONSISTENCY

Shih (3) proposed a method for assessment of consistency to determine whether the study is capable of bridging the foreign data to the new region. Again, we only focus on the trials for comparing a test product and a placebo control. Suppose there are K reference studies in the CCDP. Based on the K historical reference studies, the test product has been already approved in the original region due to its proven efficacy against placebo control.

Let x_{ij} be some efficacy responses for the j^{th} patient receiving the test product in the i^{th} historical trial, $i = 1, \dots, K$, and $j = 1, \dots, m_i$ and y_{ij} the efficacy responses for j^{th} patient receiving the placebo control in the i^{th} historical trial, $i = 1, \dots, K$, and $j = 1, \dots, n_i$. Then the treatment group difference in means for the i^{th} study is

$$\omega_i = \bar{x}_i - \bar{y}_i,$$

where $\bar{x}_i = \frac{1}{m_i} \sum_{j=1}^{m_i} x_{ij}$ and $\bar{y}_i = \frac{1}{n_i} \sum_{j=1}^{n_i} y_{ij}$ are the sample means of the m_i and n_i observations in the drug and the placebo group, respectively. Consequently, the standardized treatment difference in means for the i^{th} study can be expressed by

$$T_i = \frac{\omega_i}{s_i \sqrt{\frac{1}{m_i} + \frac{1}{n_i}}}, \quad (3)$$

where s_i is the pooled sample standard deviation of the i^{th} trial. Note that T_i approximately follows a normal distribution with mean μ and variance 1 with sufficient sample sizes. Let $T = (T_1, \dots, T_K)$ be the results of the K reference studies. Also let $\mathbf{w} = (\omega_1, \dots, \omega_K)$.

Let x_{Br} and y_{Bs} be the efficacy responses for patients r and s receiving the test product and the placebo control respectively from the bridging study conducted in the new region, $r = 1, \dots, m_B$, and $s = 1, \dots, n_B$. Let v be the treatment group difference in means for the bridging study. That is,

$$v = \bar{x}_B - \bar{y}_B,$$

where $\bar{x}_B = \frac{1}{m_B} \sum_{r=1}^{m_B} x_{Br}$ and $\bar{y}_B = \frac{1}{n_B} \sum_{s=1}^{n_B} y_{Bs}$. Let T_B be the standardized treatment difference in means of the bridging study conducted in the new region. That is

$$T_B = \frac{v}{s_B \sqrt{\frac{1}{m_B} + \frac{1}{n_B}}},$$

where s_B is the pooled sample standard deviation of the bridging study.

Shih (3) constructed the predictive probability function, $p(T_B | T)$, which provides a measure of plausibility of T_N given the previous results T and also constructed the predictive probability functions, $p(T_i | T)$, for $i = 1, \dots, K$. The result T_N from the bridging study is consistent with the reference result T if and only if

$$p(T_N | T) \geq \min \{p(T_i | T), i = 1, \dots, K\}.$$

Similar to Shih (3), Tsou et al. (4) construct the predictive probability function, $p(v | \mathbf{w})$, which provides a measure of plausibility of v given the previous results $\mathbf{w}$. In addition, $p(\omega_i | \mathbf{w})$ for $i = 1, \dots, K$ can also be constructed. The result v is consistent with the reference result $\mathbf{w}$ if and only if

$$p(v | \mathbf{w}) \geq \rho_B \min \{p(\omega_i | \mathbf{w}), i = 1, \dots, K\},$$

for some pre-specified $\rho_B > 0$. Here ρ_B represents the magnitude of consistency trend.

WEIGHTED Z-STATISTICS

Lan, Soo et al. (5) introduced the weighted Z-tests in which the weights may depend on the prior observed data for the design of bridging studies. As seen in Section 2, T_O and T_N are approximately distributed as a standard normal distribution, $N(0, 1)$, for reasonable sample sizes. The weighted Z-test with constant $0 \leq w \leq 1$, is expressed as

$$Z_w = \sqrt{w}T_O + \sqrt{1-w}T_N.$$

The condition $|Z_w| > z_{1-\alpha/2}$ implies the bridging study conducted in the new region is consistent with the study conducted in the original region. Note that the weighted Z-test combines two Z-values from two different studies conducted in different ethnic populations.

USE OF PRIOR INFORMATION FOR BAYESIAN EVALUATION

To minimize unnecessary duplication of generating clinical data in the new region, the sponsor may borrow “strength” from the information on dose response, efficacy, and safety from the CCDP in the original region and incorporate them into the analysis of the additional data obtained from the bridging study. Hsiao, Hsu et al. (6) therefore proposed

a Bayesian approach by considering a mixture model for the prior information of Δ_N in Section 2 to synthesize the data generated by the bridging study and foreign clinical data generated in the original region for assessment of similarity. More specifically, the proposed mixture model of the prior information for Δ_N is a weighted average of two priors as given below

$$\pi(\Delta_N) = \gamma \pi_1(\Delta_N) + (1-\gamma) \pi_2(\Delta_N), \quad (4)$$

where $0 \leq \gamma \leq 1$. In (4), $\pi_2(\cdot)$ is a normal prior with mean θ_0 and variance σ_0^2 summarizing the foreign clinical data about the treatment difference obtained from the CCDP, whereas $\pi_1(\cdot) \equiv c$. Here $\pi_1(\cdot)$ is a noninformative prior which represent no information will be borrowed from the CCDP.

Given the data from the bridging study and prior information, similarity on efficacy in terms of a positive treatment effect for the new region can be concluded if the posterior probability of similarity

$$P_{SP} = P(\mu_{NT} - \mu_{NP} > 0 | \text{bridging data and prior}) > \tau,$$

for some pre-specified τ . Here the value of τ may be determined by the negotiation between the sponsor and the regulatory agency of the new region, and should generally ensure that posterior probability of similarity is at least 80%. On the other hand, selection of weight, γ should reflect the difference in both intrinsic and extrinsic ethnic factors defined in ICH E5 between the new and original regions.

CONCLUSION

In this entry, we reviewed some statistical methods for bridging studies. In the first part, we reviewed the strategy proposed by Shao and Chow (2) for determining whether a bridging study is needed for providing substantial evidence in the new region based on the clinical results observed in the original region. In the last three part, we reviewed statistical methods developed by Shih (3), Lan, Soo et al. (5), and Hsiao, Hsu et al. (6) for assessing the similarity between a bridging study conducted in a new region and studies conducted in the original region. Determination of sample size required for the bridging study can also be found in their work.

Abstract

This entry discusses calibration for obtaining analytical results and its statistical validity and also summarizes statistical methods for assessment of performance characteristics for assay validation.

INTRODUCTION

When a new pharmaceutical compound is discovered, most regulatory agencies such as the United States Food and Drug Administration (FDA) require that an analytical method or test procedure for quantitation of the active ingredients of the compound be developed and validated before it can be applied to animal or human subjects.^[1] The FDA current Good Manufacturing Practice (cGMP) requires that test methods, which are used for assessing compliance of pharmaceutical products with established specifications, must meet proper standards of accuracy and reliability. The General Chapter of the United States Pharmacopeia and National Formulary (USP/NF) defines the validation of analytical methods as the process by which it is established, in laboratory studies, that performance characteristics of the methods meet the requirements for the intended analytical application.^[2] The performance characteristics include accuracy, precision, limit of detection (LOD), limit of quantitation (LOQ), selectivity (or specificity), linearity, range, and ruggedness. These performance characteristics are often used for assessment of accuracy and reliability of the test results obtained from the analytical methods or the test procedures. The analytical application may be referred to as a drug potency, which is usually based on gas chromatography (GC) or high-performance liquid chromatography (HPLC) for potency and stability studies, immunoassays such as radioimmunoassay (RIA) for the *in vitro* activity of an antibody or antigen, or a biological assay for the *in vivo* activity such as median effective dose (ED_{50}).

To assure the accuracy and reliability of the test results obtained from the analytical method or the testing procedure based on some instruments such as HPLC, calibration of the instrument employed in the analytical method or the testing procedure is critical. In the next section, statistical methods for establishment of the standard curve in calibration for assay validation are introduced. “Calibration and Analytical Results” discusses calibration for obtaining analytical results and its statistical validity (bias and mean-squared error). “An Example” provides a summary

of statistical methods for assessment of performance characteristics for assay validation as described in the USP/NF.

STANDARD CURVE

As indicated earlier, when a new pharmaceutical compound is discovered, analytical methods or test procedures are necessarily developed for determining the active ingredients of the compound in compliance with USP/NF standards for the identity, strength, quality, purity stability, and reproducibility of the compound. An analytical method or test procedure is usually developed based on instruments such as HPLC. The cGMP indicates that an instrument must be suitable for its intended purposes and be capable of producing valid results with certain degrees of accuracy and reliability. Therefore the instrument must be calibrated, inspected, and routinely checked according to written procedures. As a result, instrument calibration is essential in order to meet the established written procedures or specifications.

A typical approach to instrument calibration is to have a number of known standard concentration preparations $\{x_i, i = 1, \dots, n\}$ put through the instrument to obtain the corresponding responses $\{y_i, i = 1, \dots, n\}$. Based on $\{x_i, y_i, i = 1, \dots, n\}$, an estimated calibration curve can be obtained by fitting an appropriate statistical model between y_i and x_i . The estimated calibration curve is usually referred to as the “standard curve.” For a given unknown sample x_0 with a response of y_0 , the concentration of x_0 can be estimated based on the established standard curve by the x value that corresponds to y_0 . Alternatively, an estimate of x_0 can also be obtained by applying the inverse regression with x_i and y_i switched. Chow and Shao^[3] studied the difference between the estimates of x_0 obtained by using the standard curve and the inverse regression.

Model Selection

For an analytical method or a test procedure, the precision and reliability of the analytical result or the test result of an

unknown sample rely on the validity and efficiency of the established standard curve that is constructed based on the selected statistical model. Therefore it is critical to select an appropriate statistical model to calibrate the instrument. Let x_i be the i th standard concentration preparation and y_i be the corresponding response from the instrument, $i = 1, \dots, n$. In practice, the following models are commonly used for establishment of standard curve:

Model	Description
1	$y_i = x_i\alpha + \beta x_i + e_i$
2	$y_i = \beta x_i + e_i$
3	$y_i = \alpha + \beta_1 x_i + \beta_2 x_i^2 + e_i$
4	$y_i = \alpha x_i^\beta e_i$
5	$y_i = \alpha e^{\beta x_i} e_i$

where α , β , β_1 , and β_2 are unknown parameters and e_i 's are independent random errors with $E(e_i) = 0$ and finite $\text{Var}(e_i)$ in models 1–3, and $E(\log e_i) = 0$ and finite $\text{Var}(\log e_i)$ in models 4 and 5.

Model 1 is a simple linear regression model that is probably the most commonly used statistical model for establishment of standard curves. When the standard curve passes through the origin, model 1 reduces to model 2. Model 3 indicates that the relationship between y_i and x_i is quadratic. When there is a nonlinear relationship between y_i and x_i , models 4 and 5 are useful. As a matter of fact, both model 4 and model 5 are equivalent to a simple linear regression model after a logarithmic transformation. It can be seen that under each of the above models, although the standard curve can be obtained by fitting an ordinary linear regression, the resultant estimates of the concentration of the unknown sample are different. Thus how to select an appropriate model among the five models has been a challenge for scientists in this area. For example, Box and Hill^[4] used a Bayesian approach to determine the true model among several candidate models. Some statistical tests of hypotheses for discriminating among models were developed by Cox^[5,6] and Atkinson.^[7] Akaike^[8] suggested an information measure to discriminate among several models. Borowiak^[9] gave a comprehensive discussion on the general issues of model discrimination for nonlinear regression models.

Because models 1–4 are polynomials and model 5 can be approximated by a polynomial, Ju and Chow^[10] recommended the following ad hoc procedure for model selection using a sequential hypotheses testing approach:

Step 1: If the number of levels of standard concentration is less than 4, go to the next step; otherwise, start with the following polynomial regression model

$$y_i = \alpha + \beta_1 x_i + \beta_2 x_i^2 + \beta_3 x_i^3 + \beta_4 x_i^4 + e_i \quad (1)$$

Let p_{34} be the p value for testing

$$H_{034} : \beta_3 = \beta_4 = 0$$

based on the ordinary least-squares fitting of model 1. If p_{34} is greater than a predetermined level of significance, go to the next step; otherwise, go to Step 4.

Step 2: Because β_3 and β_4 are not significantly different from zero, model 1 reduces to

$$y_i = \alpha + \beta_1 x_i + \beta_2 x_i^2 + e_i \quad (2)$$

We then select a model among models 1–3. Let p_2 be the p value for testing

$$H_{02} : \beta_2 = 0$$

If p_2 is greater than a predetermined level of significance, model 3 is chosen; otherwise, go to the next step.

Step 3: If β_2 is not significantly different from zero, model 2 reduces to

$$y_i = \alpha + \beta_1 x_i + e_i$$

In this case, we select a model between models 1 and 2 by testing

$$H_{01} : \beta_1 = 0$$

If the p value for testing H_{01} is smaller than the predetermined level of significance, model 1 is chosen; otherwise, model 2 is selected.

Step 4: We select model 4 or model 5. Because models 4 and 5 have the same number of parameters, we would select the model with a smaller residual sum of squares.

Alternatively, Tse and Chow^[11] proposed a selection procedure based on the R^2 statistic and the mean-squared error of the resultant calibration estimator of the unknown sample. Their idea can be described as follows. First, fit the five candidate models using data $\{x_i, y_i, i = 1, \dots, n\}$. Then, eliminate those candidate models that fail the lack-of-fit test or significance test. For the remaining models, calculate the corresponding R^2 value, where

$$R^2 = \frac{\text{SSR}}{\text{SSR} + \text{SSE}}$$

and SSR and SSE are the sum of squares due to the regression and the sum of squares of residuals, respectively. The R^2 represents the proportion of the total variability of the responses explained by the model. It is often used as an indicator for the goodness of fit of the selected statistical model in analytical research in drug research and development.^[12] Let $R_{\max}^2$ be the maximum of the R^2 values among the remaining models. For each model, define $r = R^2/R_{\max}^2$. Eliminate those models with r value less than r_0 , where r_0 is a predetermined critical value. For the remaining models, identify the best model by comparing the mean-squared errors of the calibration estimator of the unknown concentration at x_0 based on the candidate models that would produce a given target response y_0 .

Weight Selection

For the establishment of standard curve in calibration of an instrument, larger variability is often observed in the response of a higher standard concentration preparation. If this is the case, the ordinary least-squares estimators may not be efficient. Alternatively, a weighted least-squares method is often considered to incorporate the heterogeneity of the variability. Let $Y = (y_1, \dots, y_n)'$ and $\varepsilon = (e_1, \dots, e_n)'$ under models 1–3 and $Y = (\log y_1, \dots, \log y_n)'$ and $\varepsilon = (\log e_1, \dots, \log e_n)'$ under models 4 and 5. Then, the five models described above can be written as

$$Y = X\theta + \varepsilon$$

where θ is a p vector of parameters, X is the $n \times p$ matrix whose i th row is x_i and θ and X_i for each model are given below.

Model	θ	X_i
1	$(\alpha, \beta)'$	$(1, x_i)'$
2	β	x_i
3	$(\alpha, \beta_1, \beta_2)'$	$(1, x_i, x_i^2)'$
4	$(\log \alpha, \beta)'$	$(1, \log x_i)'$
5	$(\log \alpha, \beta)'$	$(1, x_i)'$

Let W be the $n \times n$ diagonal matrix whose i th diagonal element is the weight w_i . Then, a weighted least-squares estimator of θ is

$$\hat{\theta} = (X'WX)^{-1}X'WY \quad (3)$$

Appropriate weights are usually selected so that the variance of the response at each standard concentration preparation is stabilized. Selection of an appropriate weight depends on the pattern of the standard deviation of the response at each standard concentration preparation. Let SD_x be the standard deviation of the response corresponding to the standard concentration preparation x . In practice, the following three types of weights are commonly employed for establishment of standard curve:

SD_x	Weight
σ_e	1
$\sigma_e \sqrt{x}$	$1/x$
$\sigma_e x$	$1/x^2$

where $\sigma_e > 0$ is an unknown parameter. When SD_x is a constant across all standard concentration preparations under study, no weight is necessary and W becomes the identity matrix, in which case $\hat{\theta}_w$ in formula 3 is the same as the ordinary least-squares estimator. If SD_x is proportional to $\sqrt{x}$ (or x), an appropriate choice for w_i is $1/x_i$ (or $1/x_i^2$).

For each of these three weights, the weighted least-squares estimator $\hat{\theta}_w$ is an unbiased estimator of θ with

$$\text{Var}(\hat{\theta}_w) = (X'WX)^{-1}X'W\text{Var}(\varepsilon)WX(X'WX)^{-1} \times \sqrt{b^2 - 4ac} \quad (4)$$

which reduces to $\sigma_e^2 (X'WX)^{-1}$ if the correct weight is used (e.g., $SD_x = \sigma_e \sqrt{x}$ and $w_i = 1/x_i$ is chosen).

Ju and Chow^[10] suggested to use the following model for weight selection:

$$|r_i| = \gamma_0 + \gamma_1 \sqrt{x_i} + \gamma_2 x_i + u_i, i = 1, \dots, n$$

where r_i is the i th residual from the ordinary least-squares estimation of θ and γ_j 's are unknown parameters. If we fail to reject the null hypothesis of

$$H_0 : \gamma_1 = \gamma_2 = 0$$

then no weight is necessary. When the above null hypothesis is rejected, we select the weight of $1/x^2$ if

$$SS(b_2 | b_0, b_1) > SS(b_1 | b_0, b_2)$$

where $SS(b_2 | b_0, b_1)$ is the extra sum of squares due to the inclusion of the term $\gamma_2 x$ provided that γ_0 and $\gamma_1 \sqrt{x}$ are already in the model. $SS(b_1 | b_0, b_2)$ is similarly defined. Otherwise, we select the weight of $1/x$.

Alternatively, we may select a weight function by minimizing an estimated $\text{Var}(\hat{\theta}_w)$ given by model 4 because the true variance of $\hat{\theta}_w$ is minimized when the correct weight is selected. Let $W_j, j = 0, 1, 2$, be the weight matrix W corresponding to the selection of weight functions 1, $1/x$, $1/x^2$, respectively. An approximately unbiased estimator of $\text{Var}(\hat{\theta}_{W_j})$ is

$$D_j = (X'W_jX)^{-1}X'W_j\hat{V}W_jX(X'W_jX)^{-1}$$

where $\hat{V}$ is the $n \times n$ diagonal matrix whose i th diagonal element is r_i^2 and r_i is the i th residual from the ordinary least-squares estimation. Then, the weight function corresponding to W_j is selected if $D_j = \min\{D_0, D_1, D_2\}$. It will be shown in "Calibration and Analytical Results" that choosing W by minimizing $\text{Var}(\hat{\theta}_w)$ leads to the most efficient calibration.

Note that weight selection affects the efficiency, not the bias of the estimation of θ , because any weighted least-squares estimator is unbiased as long as a correct model is chosen. On the other hand, if a wrong model is used, then all weighted least-squares estimators are biased, and they are not good estimators even if the best weights are used. Thus weight selection can be performed after a suitable model is chosen. At the model selection stage, the ordinary least-squares method can be used for simplicity.

CALIBRATION AND ANALYTICAL RESULTS

For a given unknown sample concentration x_0 with a response of y_0 , the analytical result or assay result of the unknown sample, denoted by $\hat{x}_0$, is the estimated value of x_0 obtained by finding the x value corresponding to y_0 on the established standard curve. For example, if model 1 is used, then

$$\hat{x}_0 = (y_0 - \hat{\alpha}) / \hat{\beta}$$

where $\hat{x}$ and $\hat{\beta}$ are the ordinary or weighted least-squares estimators of α and β . In general,

$$\hat{x}_0 = h(y_0, \hat{\theta}_w)$$

where $\hat{\theta}_w$ is the weighted least-squares estimator of θ given by formula 3 under one of the five models in the subsection “Weight Selection” and h is a function depending on the model. The functions h for the five models described above are given as follows:

Model	θ	$h(y_0, \theta)$
1	$(\alpha, \beta)'$	$(y_0 - \alpha) / \beta$
2	β	y_0 / β
3	$(\alpha, \beta_1, \beta_2)'$	$[-\beta_1 \pm \sqrt{\beta_1^2 - 4\beta_2(\alpha - y_0)}] / (2\beta_2)$
4	$(\log \alpha, \beta)'$	$(y_0 / \alpha)^{1/\beta}$
5	$(\log \alpha, \beta)'$	$(\log y_0 - \log \alpha) / \beta$

Note that under model 3, there may be two x values corresponding to a single y_0 . One of these x values, however, is usually outside of the study range of x and thus the other x value is $\hat{x}_0$.

In general, $\hat{x}_0$ is not exactly equal to x_0 because of two sources of variability: the variation due to the response y_0 and the statistical variation in the construction of the standard curve. The variability of an estimator is usually assessed by its bias and mean-squared error. For $\hat{x}_0$, however, its exact first and second moments may not exist because h is a nonlinear function of θ . Thus we may use asymptotic (large n) bias and mean-squared error of $\hat{x}_0$ to assess its variability. The asymptotic bias of $\hat{x}_0$ is

$$\text{bias}_{x_0} = E_{y_0}[h(y_0, \theta)] - x_0$$

Where E_{y_0} is the expectation with respect to y_0 . Under models 1 and 2, h is linear in y_0 and, hence

$$\text{bias}_{x_0} = h(E(y_0), \theta) - x_0 = 0$$

that is, $\hat{x}_0$ is asymptotically unbiased. Similarly, $\hat{x}_0$ is asymptotically unbiased under model 5. Under model 3 or 4, $\hat{x}_0$ is slightly biased because h is nonlinear in y_0 . Similarly, the asymptotic mean-squared error of $\hat{x}_0$ is

$$\text{mse}_{x_0} = E_{y_0}[h(y_0, \theta) - x_0]^2 + E_{y_0}\left[H(y_0, \theta)' \text{Var}(\hat{\theta}_w) H(y_0, \theta)\right] \quad (5)$$

where $H(y_0, \theta) = \partial h(y_0, \theta) / \partial \theta$. Under model 1, for example,

$$\text{mse}_{x_0} = \frac{1}{\beta^2} \left\{ \text{Var}(y_0) + E_{y_0} \left[\left(1, \frac{y_0 - \alpha}{\beta} \right) \text{Var}(\hat{\theta}_w) \left(1, \frac{y_0 - \alpha}{\beta} \right)' \right] \right\}$$

And in the case of constant weight function, it reduces to

$$\text{mse}_{x_0} = \frac{\sigma_e^2}{\beta^2} \left[1 + \frac{1}{n} + \frac{(x_0 - \bar{x})^2 + \sigma_e^2 / \beta^2}{S_{xx}} \right] \quad (6)$$

where $\bar{x}$ is the average of x_i 's and $S_{xx} = \sum_{i=1}^n (x_i - \bar{x})^2$.

A result similar to formula 6 is given by Buonaccorsi.^[13]

Formula 5 also indicates that we should select the weight matrix W by minimizing $\text{Var}(\hat{\theta}_w)$ which yields the most efficient estimator $\hat{x}_0$. Note that formula 5 is still valid even if an incorrect weight function is used. However, this formula is not valid if a wrong model is selected.

Formula 5 or 6 can be used to determine the sample size n in establishing the standard curve. For example, Buonaccorsi and Iyer^[14] suggested three criteria for choosing n : V optimality, which concerns mse_{x_0} ; AV optimality, which concerns an average of mse_{x_0} over x_0 with respect to a distribution of x_0 ; and M optimality, which concerns the maximum of mse_{x_0} over a range of x_0 .

When there are some independent replicates at x_0 , which yield several estimates of x_0 , the asymptotic mean-squared error of $\hat{x}_0$ can be estimated. Without replicates, we can still estimate mse_{x_0} but some derivations are necessary. We illustrate this in the following example.

AN EXAMPLE

Table 1 contains 12 standard concentration preparations and their corresponding absorbances (the y responses) in a potency test of a drug product. The response y_0 corresponding to the unknown sample concentration x_0 is also included in Table 1. The results in Table 1 are in the actual order of the runs.

Ju and Chow's model and weight selection procedure described above was applied to select a model and weight function, which results in model 1 with constant variance. The standard curve is

$$y = -2.358 + 5.429x$$

with $R^2 = 0.966$ and $\hat{\sigma}_e = 3.987$. With $y_0 = 90.044$, we obtain that

$$\hat{x}_0 = 17.020$$

Table 1 Calibration data

Concentration ($\mu\text{g ml}^{-1}$)	Absorbance (area)
17.65(L)	97.485
17.65(L)	95.406
22.06(M)	121.200
22.06(M)	121.968
26.47(H)	142.346
26.47(H)	145.464
x_0	90.044
26.47(H)	141.835
26.47(H)	135.625
22.06(M)	113.814
22.06(M)	112.890
17.65(L)	89.872
17.65(L)	90.964

Note that under model 1 with constant variance, $\hat{x}_0$ is asymptotically unbiased with mse_{x_0} given by formula 6. mse_{x_0} can be estimated by replacing σ_e^2/β^2 in formula 6 by $\hat{\sigma}_e^2/\hat{\beta}^2 = 3.987^2/5.429^2 = 0.539$. Formula 6 also involves x_0 . If x_0 in formula 6 is replaced by $\hat{x}_0$ then we obtain the following estimate of mse_{x_0} :

$$\widehat{\text{mse}}_{x_0} = \frac{\hat{\sigma}_e^2}{\hat{\beta}^2} \left[1 + \frac{1}{n} + \frac{(\hat{x}_0 - \bar{x})^2 + \hat{\sigma}_e^2/\hat{\beta}^2}{S_{xx}} \right] = 0.674$$

A slightly different estimator according to Buonaccorsi^[13] is

$$\widetilde{\text{mse}}_{x_0} = \frac{\hat{\sigma}_e^2}{\hat{\beta}^2} \left[1 + \frac{1}{n} + \frac{(\hat{x}_0 - \bar{x})^2}{S_{xx}} \right] = 0.672$$

which is motivated by the fact that

$$\begin{aligned} E_{y_0} (\hat{x} - \bar{x})^2 &= E_{y_0} \left(\frac{y_0 - \hat{\alpha}}{\hat{\beta}} - \bar{x} \right)^2 \\ &= \frac{E_{y_0} (y_0 - \hat{\alpha} - \hat{\beta}\bar{x})^2}{\hat{\beta}^2} \\ &\approx \frac{E_{y_0} (y_0 - \alpha - \beta\bar{x})^2}{\beta^2} \\ &= (x_0 - \bar{x})^2 + \sigma_e^2/\beta^2 \end{aligned}$$

Note that $\widetilde{\text{mse}}_{x_0}$ is slightly more conservative than $\widehat{\text{mse}}_{x_0}$.

APPLICATION IN ASSAY VALIDATION

As indicated by the USP/NF, the validation of an analytical method or a test procedure can be carried out by assessing a set of performance characteristics or analytical

validation parameters. These validation parameters include accuracy, precision, limit of detection, limit of quantitation, selectivity, range, linearity, and ruggedness. Shah et al.^[15] recommended that an analytical method be considered validated in terms of accuracy if the mean value is within $\pm 15\%$ of the actual value. Similarly, it is also suggested that the analytical method be considered validated in terms of precision if the precision around the mean value does not exceed a 15% coefficient of variation (CV). One may use the same 15% criterion for other validation parameters, except for the limit of quantitation, where it should not deviate from the actual value by more than 20%.

In practice, the validation of an analytical method is usually carried out by the following steps: First, it is important to develop a prospective protocol that clearly states the validation design, sampling procedure, acceptance criteria for the performance characteristics to be evaluated, and how the validation is to be carried out. Second, collect the data and document the experiment, including any violations from the protocol that may occur. The data should be audited for quality assurance. The collected data are then analyzed based on appropriate statistical methods. Appropriate statistical methods are referred to as those methods that can reflect the validation design and meet the study objective. Finally, draw a conclusion regarding whether the analytical method is validated based on the statistical inference drawn about the accuracy, precision, and ruggedness of the assay results. In this section, we define each validation parameter and provide a description of standard statistical method for assessment of the validation parameter.

Accuracy

The accuracy of an analytical method or a test procedure is defined as the closeness of the result obtained by the analytical method or the test procedure to the true value. In practice, the bias is often considered as the primary measure for closeness in the assessment of assay accuracy.

In the validation of an analytical method, the accuracy of an analytical method is usually assessed through the conduct of a recovery study. In a recovery study, the analytical method is applied to samples or mixtures of excipients, which usually consist of known amounts of analyte that are added both above and below the normal levels expected in the samples. The analytical method employed recovers the active ingredients from the excipients. The recovered added amount of active ingredients are usually expressed as a percent of a label claim. A recovery study is typically conducted on three separate days. Three assay results are obtained on each day. Let y_{ij} be the assay result obtained by the analytical method when the known amount of analyte is x_{ij} , where i is the index for day. The percent recovery of x_{ij} is defined to be $z_{ij} = y_{ij}/x_{ij}$, which is assumed to follow a one-way random effects model

$$z_{ij} = \mu_z + D_i + e_{ij}, \quad i = 1, 2, 3, \quad j = 1, 2, 3 \quad (7)$$

where μ_z is an unknown parameter, D_i 's are independently distributed as $N(0, \sigma_D^2)$, e_{ij} 's are independently distributed as $N(0, \sigma_e^2)$ and D_i 's and e_{ij} 's are mutually independent. Note that σ_D^2 and σ_e^2 are known as the between-day (or day-to-day) variability and the within-day (or intraday) variability, respectively.

Using the criteria recommended by Shah et al.,^[15] the analytical method is validated in terms of accuracy if $85\% < \mu_z < 115\%$. Thus if a 95% confidence interval based on the recovery data is within the interval (85%, 115%), then the analytical method is considered validated. In practice, the largest possible bias (i.e., either the lower or upper limit of the 95% confidence interval for the mean) is often reported in assay validation for accuracy.

Because model 7 is a balanced one-way random effects model, the best unbiased estimator of μ_z is $\bar{z} = \sum_{ij} z_{ij} / 9$. A 95% confidence interval for μ_z is

$$\left(\bar{z} - t_{0.975;2} s_D / \sqrt{3}, \bar{z} + t_{0.975;2} s_D / \sqrt{3} \right)$$

where $s_D^2 = \sum_{i=1}^3 (\bar{z}_i - \bar{z})^2$, $\bar{z}_i = \sum_{j=1}^3 z_{ij} / 3$, and $t_{0.975;r}$ is the 97.5th percentile of the t distribution with r degrees of freedom.

The accuracy of an analytical method can also be assessed by a statistical analysis of the standard curve corresponding to the analytical method. For example, when the standard curve is given by a simple linear regression model, i.e.,

$$y_i = \alpha + \beta x_i + e_i$$

Bohidar^[16] and Bohidar and Peace^[17] suggested that the accuracy of an analytical method be assessed by testing the following hypotheses:

$$\begin{array}{ll} H_{01} : \beta = 0 & \text{vs. } H_{11} : \beta \neq 0. \\ H_{02} : \beta = 1 & \text{vs. } H_{12} : \beta \neq 1. \\ H_{03} : \alpha = 0 & \text{vs. } H_{13} : \alpha \neq 0. \end{array}$$

The first set of hypotheses is used to quantify a significant linear relationship between recovered (or found) and added amounts (input). This is because an analytical method cannot be validated if no relationship between found and input exists. The second set of hypotheses is used to verify whether the change in 1 unit of the added amount will result in the change in 1 unit of the recovered amount. The third set of hypotheses is to make sure that the analytical method does not recover any active ingredient if it is not added.

Precision

The precision of an analytical method or a test procedure is referred to as the degree of closeness of the result obtained by the analytical method or the test procedure to the true value. In practice, the total variability associated with the

assay result is often considered as the primary measure for the assessment of assay precision.

The assessment of assay precision can be carried out by using the data from a recovery study. Under model 7, the total variability, the between-day (or day-to-day) variability, and the within-day variability of the analytical method can be estimated. Using the method of analysis of variance (ANOVA), we obtain the following estimator of within-day variance σ_e^2 :

$$\hat{\sigma}_e^2 = \frac{1}{6} \sum_{i=1}^3 \sum_{j=1}^3 (z_{ij} - \bar{z}_i)^2$$

and the following estimator of between-day variance σ_D^2 :

$$\hat{\sigma}_D^2 = s_D^2 - \hat{\sigma}_e^2 / 3$$

Because an ANOVA estimate may lead to a negative estimate for the between-day variance σ_D^2 , the method of restricted maximum likelihood (REML), which truncates the ANOVA estimate at zero, is usually considered as an alternative to the ANOVA estimate. To avoid a negative estimate, it is recommended that the method proposed by Chow and Shao^[18] be used.

The total variability of an analytical method, $\sigma_T^2 = \sigma_D^2 + \sigma_e^2$, can be estimated by

$$\hat{\sigma}_T^2 = \frac{1}{8} \sum_{ij} (z_{ij} - \bar{z})^2$$

If an analytical method is considered validated in terms of precision when the total variability is less than a predetermined σ_0^2 , then we may claim that the analytical method is validated if $8\hat{\sigma}_T^2 / \chi_{0.95;8}^2 < \sigma_0^2$, where $\chi_{0.95;r}^2$ is the 95th percentile of the chi-square distribution with r degrees of freedom and $8\hat{\sigma}_T^2 / \chi_{0.95;8}^2$ is a 95% confidence bound for σ_T^2 .

Other Performance Characteristics

Other performance characteristics of an analytical method or a test procedure that are commonly considered in assay validation include ruggedness, specificity, linearity, range, limit of detection, and limit of quantification. These performance characteristics are briefly described below. More details can be found in Refs. [2, 16–18].

The ruggedness of an analytical method usually refers to the degree of reproducibility of the analytical results obtained by analysis of the same sample under a variety of normal test conditions such as different laboratories, different instruments, different analysis, different lots of reagents, different elapse times, different assay temperatures, and different days. Ruggedness is often used to assess the influence of uncontrollable factors or the degree of reproducibility on assay performance. Typical approaches for assessing assay ruggedness include the one-way nested random-effects model and the two-way

crossed-classification mixed model. For the assessment of assay ruggedness, it should be noted, however, that the classical analysis of variance method may produce negative estimates for the variance components and that the sum of best estimates of variance components may not be the best estimate of the total variability. In these situations, methods proposed by Chow and Shao^[19] and Chow and Tse^[20] are useful.

The specificity, which is also known as selectivity, is defined as the ability of an analytical method to accurately measure the analyte, specifically in the presence of components that may be expected to be present in the sample matrix. Specificity is often expressed as the difference in assay results obtained by analysts of samples containing added impurities, degradation products, related chemical compounds, or placebo ingredients to those from samples without added substances. Hence specificity is a measure of the degree of interference in analysis of complex sample matrix. An acceptable method should be free of any significant interference by substances known to be present in the drug product.

The linearity of an analytical method is defined as the ability to elicit assay results that are directly proportional to the concentration of analyte in samples within a given range. The range of an analytical method is the interval between the upper and lower levels (inclusive) of analyte that have been determined with accuracy, precision, and linearity using the method as written.

The limit of detection is defined as the lowest concentration of analyte in a sample that can be detected, but not necessarily quantitated, under the experimental conditions specified. In other words, LOD denotes the amount of analyte that can be reliably distinguished from background with certain assurance. Let x be the amount of analyte and y be the response. Suppose that $x = 0$ corresponds to the background and the standard curve passes through the origin. Then, the following $100(1 - a)\%$ upper confidence limit of the mean response at background,

$$LC = z_{1-a}\sigma_0$$

can be viewed as a critical limit (LC) for detecting an analyte from background, where z_{1-a} is the $(1 - a)$ th quantile of the standard normal distribution and σ_0^2 is the variance of a response at background. An amount of analyte x is considered to be detectable from the background if and only if the probability that a response at x falls below the critical limit is less than a . Thus the limit of detection, LOD, for a given analyte is the x value corresponding to $LC = z_{1-a}\sigma_D$, i.e.,

$$LOD = \frac{LC + z_{1-a}\sigma_D}{\beta} \quad (8)$$

where β is the slope of the calibration curve and σ_D is the standard deviation of the response at the detectable analyte in the sample. Alternatively, the ICH guideline

for validation of analytical procedures suggests that the concept of the signal-to-noise ratio be applied for estimating the detection limit.^[21] The concept of the signal-to-noise ratio is to compare signals obtained from samples with known low concentrations of analyte with those of blank (background) samples and establishing the minimum concentration at which the analyte can be reliably detected. The ICH guideline indicates that a signal-to-noise ratio of 3.3:1 is generally considered acceptable for establishing the detection limit. This leads to

$$LOD = \frac{3.3\sigma_D}{\beta} \quad (9)$$

where β is the slope of the calibration curve. It should be noted that formula 8 is equivalent to formula 9 if $a = 5\%$ and $\sigma_0 = \sigma_D$.

The limit of quantitation is the lowest concentration of an analyte in a sample that can be determined with acceptable precision and accuracy under the experimental condition specified. In practice, the lowest concentration of an analyte in a sample is usually defined as that for which the relative standard deviation is 10%. This leads to a signal-to-noise ratio of 0.1. As a result, the limit of quantitation can be obtained by

$$LOQ = \frac{10\sigma_D}{\beta}$$

It should be noted, however, that although a relative standard deviation of 10% is considered an acceptable standard in chemical assays in practice, 10% RSD is often unachievable in biological assays. About 20–25% variability is generally sought in binding assays, while much higher levels are more realistic in bioassay.

CONCLUSION

The validation of an analytical method or a test procedure is usually carried out by assessing a set of performance characteristics or analytical validation parameters. These validation parameters include accuracy, precision, limit of detection, limit of quantitation, selectivity, range, linearity, and ruggedness. The calibration of the instrument employed in the analytical method of test procedure plays an extremely important role to assure the accuracy and reliability of the results obtained from the analytical method or test procedure.

Canadian Health Products and Food Branch (HPFB) and Therapeutic Products Directorate (TPD)

Dongsheng Tu

NCIC Clinical Trials Group, Queen's University, Kingston, Ontario, Canada

Abstract

The objective of this entry is to provide an overview of the activities within HPFB that are related to biopharmaceutical products intended for human use with a focus on TPD.

INTRODUCTION

Health Canada, the Canadian federal department with a mission to help the people of Canada maintain and improve their health, had a major organizational realignment in July of 2000. The former Health Protection Branch (HPB) was divided into several new branches. The Health Products and Food Branch (HPFB) (*) is one of these new branches; its mandate is to take an integrated approach to managing the health-related risks and benefits of health products and food by minimizing health risk factors to Canadians while maximizing the safety provided by the regulatory system for health products and food and promoting conditions that enable Canadians to make healthy choices and providing information so that they can make informed decisions about their health. To fulfill this mandate, HPFB is divided into several offices and directorates. Principal directorates in HPFB include: (i) the Biologics and Genetic Therapies Directorate (BGTD), which is responsible for the regulation of biological and radiopharmaceutical drugs, including blood and blood products, viral and bacterial vaccines, genetic therapeutic products, tissues, organs, and xenografts; (ii) the Food Directorate, which is responsible for the protection and the improvement of the health of the people of Canada through science-based policies and programs related to safe and nutritious food; (iii) the HPFB Inspectorate, which is responsible for the management of inspection, investigation, monitoring activities, and enforcement strategies related to the fabrication, packaging/labeling, testing, importation, distribution, and wholesale of regulated health products for human and veterinary use; (iv) the Natural Health Products Directorate (NHPD), which is responsible for ensuring that Canadians have ready access to health products that are safe, effective, and of high quality by maintaining proper labeling and by implementing a regulatory framework that supports freedom of choice and cultural diversity; (v) the Therapeutic Products Directorate (TPD), which is responsible for the regulation of pharmaceutical drugs, medical devices, and

other therapeutic products available to Canadians; (vi) the Veterinary Drugs Directorate (VDD), which is responsible for ensuring the safety of foods such as milk, meat, eggs, fish, and honey from animals treated with veterinary drugs and for ensuring that veterinary drugs sold in Canada are safe and effective for animals; and (vii) the Marketed Health Products Directorate (MHPD), which is responsible for post-markets surveillance of all marketed health products regulated by HPFB. The objective of this entry is to provide an overview of the activities within HPFB that are related to biopharmaceutical products intended for human use with a focus on TPD.

DRUG REGULATIONS AND GUIDANCES IN CANADA

The TPD derives its legislative authorities from a range of federal statutes. The most important one is the Food and Drugs Act, which is the regulatory base for the activities in TPD. The current Food and Drug Act provides the authority to prohibit the sale of drugs and devices that are manufactured under unsanitary conditions or that are adulterated; to prohibit the false or misleading advertising, labeling, packaging, processing, and sale of drugs and devices; and to prohibit the sale of drugs and devices that do not comply with prescribed or professed standards. According to the Food and Drug Act, a “drug” includes any substance or mixture of substances manufactured, sold, or represented for use in the diagnosis, treatment, mitigation or prevention of disease, disorder or abnormal physical state, or the symptoms thereof, in human or animal; the restoration, correction, or modification of organic functions in human or animal; or the disinfections in premises in which food is manufactured, prepared, or kept. A “device” means any article, instrument, apparatus, or contrivance, including any component, part, or accessory thereof, manufactured, sold, or represented for use in the diagnosis, treatment, mitigation, or prevention of a disease, disorder

or abnormal physical state, or the symptoms thereof, in man or animal; the restoration, correction, or modification of a body function or the body structure of man or animal; the diagnosis of pregnancy in humans or animals; or the care of humans or animals during pregnancy and at and after birth of the offspring, including care of the offspring (a contraceptive device but not a contraceptive drug is included). Therefore the range of therapeutic products encompassed by the Food and Drug Act is very broad, which includes: pharmaceuticals, including prescription and over-the-counter drugs; homeopathics, herbal remedies, and nutraceuticals; biological products, such as vaccines, blood and blood products, certain hormones and enzymes, tissues and organs, and xenografts; medical devices, such as medical and dental implants, medical equipment and instruments, test kits for diagnosis, and contraceptive devices; disinfectants; low-risk products, such as sunscreen, antiperspirants, and toothpaste; and narcotic, controlled, and restricted drugs. The Food and Drugs Act was invoked in 1920, after the Inland Revenue Act of 1876, which dealt mostly with the adulteration of alcohol but without the definition of the drugs, and Adulteration Act of 1884, which for the first time defined what was a drug, and the adulteration and conditions under which adulteration might take place.^[1,2] It was amended in 1953 so that it had control of the manufacture, distribution, and sale of drugs except narcotics. In 1977, it took under its control also the drugs listed under the Proprietary or Patent Medicine Act, which was passed in 1909 because of concerns over the efficacy and the safety of secret ingredient drugs.

The regulatory control of drugs in Canada is specified in the Regulations to the Food and Drugs Act, which have the force of law and are issued under the authority of the Food and Drugs Act. It is also the vehicle for introducing technical changes to the Act and may include a revocation of an existing regulation, the amendment of an existing regulation, or a new regulation. According to the Food and Drug Regulations, new pharmaceutical drugs and biological products (referred only as “drugs” from now on) cannot be marketed in Canada without a Notice of Compliance (NOC) from Health Canada verifying that the manufacture and the sale of the new drug are in compliance with Food and Drugs Act and Regulations. Medical devices, cosmetics, and “old” drugs must also meet departmental safety standards.

There were many amendments to the Food and Drug Act and Regulations. An important one was made in June 2001, which introduced: (i) a 30-day default review period for an application to sell a drug for the conduct of human drug clinical trials in Canada in Phases I–III of development; (ii) clear and transparent requirements to sponsors for application, information, amendments, notification, labeling, record keeping, and adverse drug reaction reporting; (iii) an inspection system against internationally accepted good clinical practice principle and good manufacturing

practices; and (iv) a clear authority to refuse an application, to suspend, or to cancel the sale of drugs for use in clinical trials in Canada where they do not meet the updated regulatory requirements.

There are also some other federal legislations and regulations that are important to TPD: for example, Patented Medicines (Notice of Compliance) Regulations require that a company wishing to sell a generic version of another company’s drug must address that company’s patents before obtaining marketing approval to sell the generic version, and the Controlled Drugs and Substances Act (CDSA), which came into effect in 1997 and replaced the Narcotic Control Act of 1961 and parts of the Food and Drugs Act, prohibits the possession, double doctoring, trafficking, possession for the purpose of trafficking, importation, exportation, and possession for the purpose of export and production of listed psychotropic substances.

Except for the Food and Drugs Act and Regulations, there are also many guidance and policy documents issued by the TPD. These documents do not have the force of the law, but reflect the thinking of TPD on some matters interesting to sponsors and provide directions to some specific issues. A detailed list of TPD guidelines and policies can be found on the website: <http://www.hc-sc.gc.ca/dhp-mps/prodpharma/legislation/index-eng.php>.

RELATIONSHIP BETWEEN THERAPEUTIC PRODUCTS DIRECTORATE AND INTERNATIONAL CONFERENCE ON HARMONIZATION

Canada, represented by the TPD, is the sole observer country in the International Conference on Harmonization of Technical Requirements for the Registration of Pharmaceuticals for Human Use (ICH), which allows the TPD to participate in discussions of both the steering committee and the expert working groups of ICH. The TPD is committed to the consultation on, and the implementation of, ICH products (guidelines and other documents) in a timely, transparent, and expeditious manner. The general guiding principle is that ICH products will be implemented “as is” (i.e., “without modification”). In the circumstances when the scope and the subject matter of TPD guidelines are not entirely consistent with those of the ICH guidances, the ICH guidances adopted by the TPD will take precedence and corresponding TPD guidelines may be amended or withdrawn, depending on the extent of inconsistencies. For example, the TPD 1989 guideline “Conduct of Clinical Investigations” was superseded by the ICH guidance E6, “Good Clinical Practice: Consolidated Guideline,” adopted by the TPD in 1997.

But in exceptional circumstances, an ICH product maybe amended by TPD, based on considerations of special (e.g., indigenous) populations or the potential impact

of difference in the practice of medicine or in risk assessment/management models, or may not be adopted if the adoption would hinder its ability to ensure the safety and health of Canadians. Sometimes, the TPD may find it necessary to clarify the principles expressed in the ICH guidance in order to provide sufficient operational detail to the industry and the stakeholders regarding technical requirements. In these circumstances, directorate-specific statements will be captured in the TPD foreword and/or addendum to the ICH guidances. For example, in the TPD foreword to ICH guidance E6, there is a TPD-specific statement that deals with the principles outlined in the section of ICH guidance E6 on the responsibilities and functions of the Institutional Review Board/Independent Ethics Committee. The statements emphasize that while ICH principles will generally be respected, “it is recognized that (Canadian) provincial/regional policies and laws may supersede them.” Also, because ICH guidance M3 recognizes the regional differences in the timing of reproduction toxicity studies to support the inclusion of women of childbearing potential in clinical trials and because there is no general principle outlined, a statement in the TPD foreword clarifies that, in Canada, the principles outlined in the TPD guideline “Inclusion of Women in Clinical Trials” should be followed. The expansion of the scope of the TPD-adopted ICH guidances beyond that expressed in these guidances is usually handled through the publication of separate, parallel TPD guidance documents. For example, TPD guidances “Identification, Qualification, and Control of Related Impurities in Existing Drugs” and “Identification, Qualification, and Control of Related Impurities in New Drugs” were developed by the TPD as companion documents to ICH guidances Q3A and Q3B, respectively, to provide further guidance on TPD’s requirements regarding the identification, qualification, and control of related impurities in “existing” and new drugs, respectively.

All the ICH guidances adopted by the TPD with its foreword can be found on the website: <http://www.hc-sc.gc.ca/dhp-mps/prodpharma/applic-demande/guide-ld/ich/index-eng.php>.

REVIEWING PROCESS AND STRUCTURE OF THE THERAPEUTIC PRODUCTS DIRECTORATE

As mentioned before, the TPD is the national authority that evaluates and monitors the safety, effectiveness, and quality of drugs, medical devices, and other therapeutic products available to Canadians. In Canada, prior to the commencement of clinical trials involving drugs intended for humans and conducted outside the approved indication, the sponsor is required to submit a Clinical Trial Application (CTA), which requests permission to distribute the drug to responsible clinical investigators who are

named in the application, to the TPD for review. Some of the information contained in a CTA includes the results from preclinical tests, production methods, dosage form, and information regarding the investigators who will be conducting the study. As mentioned before, the regulation requires the TPD to review the CTA within 30 days. If the TPD does not respond with a letter of objection within the 30-day period, the sponsor may proceed with the trial. If clinical trial results showed that the drug has potential therapeutic value that outweighs the risks associated with its use (e.g., adverse effects, toxicity), the sponsor may choose to file a New Drug Submission (NDS) with the TPD to seek the approval of marketing the drug in Canada. The NDS contains information and data about the drug’s safety, effectiveness, and quality. It includes the results of the preclinical and clinical studies, the details regarding the manufacture of the drug, packaging, and labeling details, and the information regarding therapeutic claims and side effects. After receiving the application, respective reviewing bureaus within the TPD first screen all the materials submitted for acceptability. If deficiencies are identified during the screening, a Screening Deficiency Notice identifying the deficiencies will be sent to the sponsor. Otherwise, the TPD will start performing a thorough review of submitted information, sometimes using external consultant and advisory committees, which evaluate the safety, efficacy, and quality data to assess the potential benefits and risks of the drug. The TPD also reviews the information that the sponsor proposes to provide to health care practitioners and consumers about the drug (e.g., the label, product brochure). If, upon the completion of the review, the conclusion is that the benefits outweigh the risks and that the risks can be mitigated, the drug is issued an NOC, as well as a Drug Identification Number (DIN), which permits the sponsors to market the drug in Canada and indicates the drug’s official approval in Canada. In addition, Health Canada laboratories may test certain biological products before and after the authorization to sell in Canada has been issued. This is done through its Lot Release Process, in order to monitor the safety, efficacy, and quality. If there is insufficient evidence to support the safety, efficacy, or quality claims, the TPD will not grant a marketing authorization for the drug. If this happens, the sponsor has the opportunity to supply additional information, to resubmit its submission at a later date with additional supporting data, or to appeal the TPD’s decision. The length of time for review depends on the product being submitted and the size and quality of the submission, and is influenced by the TPD’s workload and human resource.^[3] Currently, the process for the review of a drug takes an average of 18 months from the time that a submission is accepted until the TPD makes a marketing decision. For most of the NDS for the new active substance, the TPD has set 300 calendar days as the target performance standard for the review.^[4] For some

promising drug products for life-threatening or severely debilitating conditions, such as cancer, AIDS, or Parkinson's disease, for which there are few effective therapies available in the market, the TPD has a Priority Review Process in place, which allows for a faster review (with a target of 180 days). There is also a Special Access Program (SAP) administered by the TPD, which allows physicians to gain access to drugs that are not currently available in Canada. Following approval by the SPA, a physician may prescribe such a drug to specified patients, if it is the physician's belief that conventional therapies have failed or are inappropriate. The drug is only released after the TPD has determined that the need is legitimate and that a qualified physician is involved. Once a new drug is on the market, regulatory controls continue (maybe by different directorates in the HPFB such as the HPFB Inspectorate and the MHPD). The distributor of the drug must report any new information received concerning serious side effects, including the failure of the drug to produce the desired effect. The distributor must also notify the HPFB about any studies that have provided new safety information. The HPFB monitors adverse events, investigates complaints and problem reports, maintains postapproval surveillance, and manages recalls, should the necessity arise.^[5] In addition, the HPFB licenses most drug production sites and conducts regular inspections as a condition for licensing. However, certain products such as natural health and homeopathic remedies, some veterinary drugs, and vitamin and mineral supplements are not subjected to these requirements.

For a medical device that is classified in Classes II–IV based on the risk associated with their use (Class I devices presents the lowest potential risk, e.g., thermometer, and Class VI devices presents the greatest potential risk, e.g., pacemakers), a Medical Device License (MDA) is required before they can be sold. Class I devices are monitored through establishment licenses, which require the establishment to provide assurance to the TPD that regulatory requirements related to postproduction activities have been met. For a device in Class II, III, and IV, an MDA is issued after the TPD reviews the Medical Device License Application (MDLA) submitted by a sponsor and finds the information provided in MDLA as meeting the requirements in the Food and Drug Act and Medical Devices Regulations. If an MDL is not issued by the TPD, the sponsor can resubmit the application and supply additional information or appeal the TPD's decision. The length of the review varies depending on the class of the device: Class III and IV license applications have a target review time of 75 calendar days, and Class II license application have a 15-calendar day target. There is also a SAP for medical devices, which allows doctors to gain access to medical devices that have not been licensed in Canada in emergency situations or when conventional therapies have failed, are

unavailable, or are unsuitable to treatment of a patient. After medical devices are licensed, they are monitored by the HPFB to ensure their continued safety and effectiveness. The license can be suspended, or the sponsor may be requested to recall or refit a medical device if it is found to be no longer safe and effective.

To make the above process more efficient, based on several external reviews,^[2,3] the TPD has also undergone major organization changes in recent years. The current structure of TPD includes three reviewing bureaus responsible for the clinical, pre-clinical, and labeling review of drug submissions indicated for use in specific therapeutic areas (the Bureau of Metabolism, Oncology, and Reproductive Sciences; the Bureau of Gastroenterology, Infection, and Viral Diseases, which is also responsible for the evaluation of pre-market applications and the management of all issues related to non-prescription drugs; and the Bureau of Cardiology, Allergy, and Neurological Sciences) and a Medical Devices Bureau that manages and conducts clinical trial reviews, pre-market reviews, licensing, and post-market assessments of medical devices; conducts research related to medical devices; conducts pre-market and post-market laboratory investigations of medical devices; and manages the SAP for medical devices. There is also a Bureau of Pharmaceutical Science that is responsible for the chemistry and manufacturing review as well as the evaluation of clinical comparative bioavailability data for all pharmaceutical products and a Bureau of Policy, Science, and International Programs that manages and coordinates the Directorate's processes for policy development, regulatory affairs, submission performance reporting, international policy development and liaison, information dissemination, expert advice and evaluation of Directorate policies, and regulations and processes. Biostatisticians are housed in the Office of Science within the Bureau of Policy, Science, and International Programs and provide statistical support for all the activities within the directorate.

CONCLUSION

In this entry, we have provided a brief description of the regulatory foundation, reviewing process of, and structure of the HPFB and TPD. As with any other organization, the structure of the HPFB and TPD is changing frequently to better meet external and internal demands and serve Canadians. Several new initiatives are being developed to amend Food and Drug Act and Regulations and to improve the drug review process. Readers are advised to check the website of both HPFB (<http://www.hc-sc.gc.ca/ahc-asc/branch-dirgen/hpfb-dgpsa/index-eng.php>) and TPD (<http://www.hc-sc.gc.ca/dhp-mps/prodpharma/index-eng.php>) for updated information about these two organizations and these initiatives.

Cancer Chemotherapy: Maximum Tolerable Dose

Jen-pei Liu

Division of Biometry, Department of Agronomy, and Institute of Epidemiology, National Taiwan University, Taipei, Taiwan; and Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan

Abstract

Statistically, the maximum tolerable dose is defined as some percentile of a tolerance distribution or dose-response curve in terms of the presence or absence of dose-limiting toxicity. This entry details how MTD can be determined in accordance with patient safety.

Keywords: Continual reassessment method; Dose limiting toxicity; Single-stage design; Two-stage design.

INTRODUCTION

The primary scientific objective of the evaluation of new chemotherapeutic agents in cancer patients during the Phase I clinical development is to employ an efficient, reliable, yet practical dose-finding design to search the highest dose with an acceptable and manageable safety profile for use in subsequent Phase II trials. This dose with an acceptable and manageable safety profile is usually referred to as the maximum tolerable dose (MTD). The unacceptable or unmanageable safety profile is generally called the dose-limiting toxicity (DLT), which is predefined by some criteria such as grade 3 or greater hematological toxicity according to the U.S. National Cancer Institute's (NCI) Common Toxicity Criteria (CTC). In short, the MTD is the highest possible but still tolerable dose with respect to some pre-specified dose limiting toxicity.^[1,2]

DEFINITION

Statistically, the MTD is defined as some percentile of a tolerance distribution or dose-response curve in terms of the presence or absence of DLT. In other words, the MTD is defined as the dose where a specified proportion of patients, say p_0 , experience DLT. Storer^[3] indicated that the value of p_0 is usually in the range from 0.1 to 0.4. Let Y be the binary response such that $Y = 1$ denote the occurrence of a predefined DLT and $\{d_i, i = 1, 2, \dots, I\}$ be a set of fixed dose levels. The relationship between the occurrence of the DLT and dose level d can be described by the following model:

$$h[P(x, \theta)] = \alpha + \beta x$$

where $h(\cdot)$ is some function of the probability of the occurrence of the DLT, x is the dose level taking one of the values d_i , and $\theta = (\alpha, \beta)'$.

The MTD is then defined as

$$x_m = (k_p - \alpha) / \beta,$$

where $k_p = h(p_0)$.

One of the commonly used functions is the logistic function. It follows that $h(p_0) = \text{logit}(p_0) = \ln[p_0/(1 - p_0)]$, where $\ln$ denotes the natural logarithm. On the other hand, the dose levels employed in phase I cancer trials for determination of the MTD are in general derived from information on animal studies. Storer^[3] pointed out that a commonly employed starting dose level is from one-tenth to one-third of the mouse LD10. In addition, the dose levels are usually selected to be approximately equally spaced on the logarithmic scale. Schneiderman,^[4] for example, suggested the use of the modified Fibonacci sequence of the diminishing multipliers of $\{2, 1.67, 1.5, 1.4, 1.33, \dots\}$.

DESIGN AND ANALYSIS

General Considerations

The primary objective of Phase I cancer trials is to establish the MTD with an adequate precision. The following considerations are important for the selection of an appropriate design for estimation of the MTD:

1. The patients are critically ill. Some of them are even in the terminal stage of the disease and the test chemotherapeutic agent may be the last hope for the patients.

2. The number of patients available for phase I cancer trials is relatively small.
3. The patient population is usually rather heterogeneous because phase I cancer trials might enroll terminal patients with different cancers.
4. Phase I cancer trials can be viewed as a screening process where cytotoxic agents with a tolerable safety profile are selected and their MTDs are determined with a minimal number of patients in a minimal amount of time.
5. Most chemotherapeutic agents generally can induce serious, irreversible, and life-threatening toxicity. Phase I cancer trials usually establish the MTD from below. In fact, regulatory agencies sometimes dictate the dose for the first patient.

Designs for phase I cancer trials generally can be classified into three categories: single-stage, two-stage, and Bayesian design. The single-stage and two-stage designs are up-and-down designs where the doses are adjusted either upward (escalation) or downward (de-escalation) within the pre-specified set of the fixed dose levels. The Bayesian approach chooses the dose level for the next patients by minimizing some measure based on the difference between the current estimate of probability for the occurrence of DLT and p_0 .

Single-Stage Design

There are three commonly employed single-stage designs for phase I cancer trials.^[1,5,6]

Design A—Standard Dose-Escalation Design

- Step 1: A group of three patients are treated at the initial dose d_1 .
- Step 2: If no pre-specified DLT is observed in all three patients, the dose for the next group of three patients is escalated to the next higher dose level. Otherwise, the next group of three patients is treated at the same dose level.
- Step 3: The dose of the next group of three patients is escalated to the next higher dose level if the pre-specified DLT is observed in at most one patient of the six patients from both Steps 1 and 2. Otherwise the trial stops.
- Step 4: Steps 2 and 3 are repeated with two consecutive groups of three patients until the trial stops.

A flowchart for Design A is given in Fig. 1.

Traditionally, if the study stops at dose level d_i , then the MTD is estimated as the next lower dose level d_{i-1} . If the trial stops at the dose level where only three patients were treated, then additional three patients should be enrolled at the next lower dose level for a total of six patients. Therefore, the MTD is the highest dose where at most one of six patients developed DLT.

Fig. 1 Flowchart for design A

It can be seen that the standard dose-escalation design only allows dose level to be escalated upward. Consequently, the starting dose level is the lowest dose level d_1 , and hence many patients are treated at doses well below the therapeutically meaningful level. Therefore, the MTD obtained from this design may be too conservative. Another drawback of this design is that because too many patients are treated at the lower dose levels, it might take a long time for the MTD to be reached. To overcome these two shortcomings of the traditional design, Storer^[5] proposed the following three designs to allow both escalation and de-escalation and to eliminate the need to use the lowest dose level as the starting dose.

Design B

- Step 1: A single patient starts at a preselected dose level.
- Step 2: If no pre-specified DLT is observed, then the next patient is treated at the same dose level. Otherwise, the next patient is treated at the next lower dose level.
- Step 3: If no pre-specified DLT occurs in both consecutive patients, then the next patient is treated at the next higher dose level. If the DLT is

observed in both consecutive patients, then the dose of the next patient is decreased to the next lower dose level. Otherwise, the trial stops.

Step 4: Repeat Steps 2 and 3 until the trial stops.

A flowchart for Design B is given in Fig. 2.

Design C

Design C is similar to Design B except that the dose level is decreased to the next dose level if the pre-specified DLT is observed in one patient, and escalation to the next higher dose level occurs only when no DLT is observed in two consecutive patients.

Design D

- Step 1: A group of three patients are treated at the initial dose $d_i, i = 1, 2, \dots, I$.
- Step 2: The dose of the next group of three patients is escalated to the next higher dose level if no DLT is observed in all three patients, or stays at the same dose level if the pre-specified DLT is observed in one patient, or decreases to the next

lower level if the DLT occurs in more than one patient.

Step 3: The trial stops when the pre-specified number of patients has completed the study.

A flowchart for Design D is given in Fig. 3.

In a simulation study, Storer^[5] reported that none of the single-stage designs performs well in an arbitrary dose-response setting with fixed sample sizes. In addition, the standard dose-escalation design even frequently failed to provide a convergent estimate for MTD. As a result, Storer^[1,5] and Simon et al.^[7] have considered a variety of combinations of traditional single-stage designs to achieve the following objectives:

- 1. To address the flaws of the standard dose-escalation design by minimizing the number of patients treated at subtherapeutic dose levels.
- 2. To concentrate sampling around the MTD.
- 3. To reduce the duration of the study.
- 4. To obtain information about interpatient variability and cumulative toxicity.

Fig. 2 Flowchart for design B

Fig. 3 Flowchart for design D

Two-Stage Design

Design BD

- Stage 1: Employ Design B until the first patient experiences DLT. Then start de-escalation with the next lower dose level until the first patient does not experience DLT.
- Stage 2: Continue the trial with Design D where the initial dose is the dose level at which the first patient does not experience DLT at Stage 1.^[5,6]

Accelerated Titration Designs

For the accelerated titration designs (ATDs), Simon et al.^[7] further grouped the toxicity grades based on the NCI's CTC into two classes: moderate toxicity for grade 0–2 and DLT for grade 3 and above. In addition, the patients will receive at least three courses of treatment in the accelerated titration designs. This type of designs consists of an initial accelerated stage and a standard dose-escalation stage.

Accelerated titration design 1 (ATD1). Initial Accelerated Stage: Cohorts of one new patient per dose level, starting at a preselected initial dose level d_1 . Dose escalation stops and reverts to the standard dose-escalation design when the first instance of the DLT is observed at the first course in one patient or two instances of moderate toxicities at the first course are observed. Dose escalation uses 40% dose-step increments. Standard Dose-Escalation Stage: Expand the cohort for current dose level to three patients and continue the trial using the traditional escalation design in a cohort of three patients. The intrapatient dose escalation is allowed if grade 0–1 toxicity is observed in the previous trial. The dose is de-escalated if grade 3 toxicity or above occurred in the previous course. Otherwise, stay at the same dose level.

Accelerated titration design 2 (ATD2). ATD2 is the same as ATD1 except that 100% dose steps are used for the initial accelerated stage.

Accelerated titration design 3 (ATD3). This design is the same as ATD2 except for the switch to the standard dose-escalation design when the first instance of the DLT is observed at any course in any patient.

Continual Reassessment Method

As mentioned above, the patients in cancer phase I trials are those with terminal cancer and at high risk of death. The characteristics of the chemotherapeutic agents evaluated in cancer phase I trials are the following: (i) they produce fatal toxicity at higher dose level; (ii) they yield no effectiveness at lower dose levels; and (iii) except for

some scarce animal data, no information about the dosing range is available. The standard dose-escalation design and one-stage or two-stage up-and-down designs update the dose for the next patient based on information on the occurrence of DLT from the current and previous patients. These designs, however, fail quantitatively using a model to combine prior information about the MTD and the information from the patients collected in the Phase I trial. To overcome these drawbacks, O'Quigley et al.^[8] have proposed the continual reassessment method (CRM) to use the Bayesian approach to estimate the MTD.

Recall that the MTD is the dose associated with the $100p_0$ percentile of the dose-response relationship with respect to the occurrence of a predefined DLT. Let $p_1, p_2, \dots, p_l$ be the initial guesses of probabilities corresponding to the set of fixed dose levels $d_1, d_2, \dots, d_l$, which are assumed to be monotonically increasing with the dose level. The dose-response relationship can then be characterized by a single-parameter, logistic regression model

$$\text{logit}[P(x_i, \beta)] = \alpha + \beta x_i$$

where the intercept α is assumed fixed, say 3,^[9–11] the slope β is to be estimated, and x_i is updated after the information of the occurrence of the DLT for the current patient becomes available using $x_i = \text{logit}^{-1}[P(x_p, \beta)]$.

- Step 1: Determine the dose-response model to be employed in the study and select a set of fixed dose levels with their corresponding occurrence probabilities. Finally, choose a fixed sample size n , say 18–24.
- Step 2: Select a prior distribution $g(\beta)$ that reflects the current brief of the investigator about the dose-response relationship. Determine the dose for the first patient as the dose level that produces the prior probability of DLT closest to the targeted probability p_0 .
- Step 3: After the result of the occurrence of DLT for the current patient at dose level x_{i-1} becomes available, obtain the Bayesian estimate of β with respect to quadratic error loss function as

$$\beta_i = E(\beta | \Lambda_{i-1}) = \int \beta f(\beta | \Lambda_{i-1}) d\beta,$$

where $f(\beta | \Lambda_{i-1})$ is the posterior density,

$$f(\beta | \Lambda_{i-1}) = q_{\Lambda_{i-1}}(\beta) g(\beta) / \int q_{\Lambda_{i-1}}(z) g(z) dz,$$

$q_{\Lambda_{i-1}}(\beta)$ is the likelihood function such that

$$q_{\Lambda_{i-1}}(\beta) = \prod [P(x_j, \beta)]^{y_j} [1 - P(x_j, \beta)]^{1-y_j}$$

and $\Lambda_{i-1} = \{(x_1, y_1), \dots, (x_{i-1}, y_{i-1})\}$, the cumulative data up to the patient receiving dose level x_{i-1} .

Step 4: Determine the dose level for the next patient by the dose level that minimizes the absolute loss function $|P(x_i, \beta_i) - p_0|$ with $x_i = \text{logit}^{-1}[P(x_i, \beta_i)]$, $i = 1, 2, \dots, I$.

Step 5: Repeat step 4 until the result of the last patient is known.

Step 6: The MTD x_m is estimated as the dose level for the hypothetical $n + 1$ patient. The corresponding probability for the occurrence of DLT can then be estimated as $P(x_m, \beta_L)$ with the corresponding $100(1 - \alpha)\%$ credibility interval given as $[P(x_m, \beta_L), P(x_m, \beta_U)]$, where (β_L, β_U) is the $100(1 - \alpha)\%$ credibility interval based on the posterior probability $f(\beta|\Lambda_m)$.

The CRM presents a revolutionary approach to estimating the MTD as compared to the traditional up-and-down method. It estimates the MTD from a continuous spectrum of doses whereas the other methods choose their MTD from a discrete set of pre-specified dose levels. In addition, the CRM utilizes a statistical model to synthesize the prior belief about the MTD and cumulative information from the trial for selection of the dose level for the next patient. However, despite these advantages, as pointed out by Korn et al.,^[2] Goodman et al.,^[9] and Ahn,^[10] the original CRM is not free of problems in its implementation for estimation of the MTD in cancer Phase I trials. First, the dose level for the next patient can be determined only after the result of the DLT for the current patient becomes available. On the other hand, the CRM only uses a cohort size of one patient for the dose adjustment. Consequently, it takes much longer time to complete the trial than the traditional dose-escalation design and most of other up-and-down designs. Secondly, the CRM might start the trial with an initial dose above the lowest dose that is often one tenth the LD10 in mice. This possibility of the initial dose above the lowest dose level for the first patient makes many clinicians uncomfortable and reluctant to implement the CRM. Another special feature of the CRM that also reduces its acceptance is the possibility that dose can be escalated for more than one dose level. This can result in that more patients may be treated at high dose levels. Møller^[12] demonstrated that the second dose can be allocated at dose level 10 even when the first patient has no DLT at the lowest dose level 1 as the initial dose.

Goodman et al.,^[9] Ahn,^[10] Ishizuka and Ohashi,^[11] O'Quigley and Shen,^[13] Heyd and Carlin,^[14] Thall et al.,^[15] and Zohar and Chevret^[16] have suggested various ways to overcome the above-mentioned shortcomings of the CRM. These improvements can be summarized as below:

1. The trial always starts with the lowest dose level as the initial dose for the first patient.
2. The size of cohorts increases to three patients.
3. The magnitude of dose escalation is limited to one dose level only between two adjacent cohorts.

4. Different accrual strategies with delayed patient outcomes are used.
5. The likelihood approach is used.
6. Different stopping rules are employed.

In addition, the CRM was modified to incorporate other information and to achieve other objectives. Ishizuka and Ohashi^[11] and Piantadosi^[17] illustrated methods to incorporate the additional pharmacokinetic data into the CRM. Legedza and Ibrahim^[18] proposed a longitudinal design for Phase I cancer trials based on the CRM to investigate the cumulative toxicity of chemotherapeutic agents. Kramar et al.^[19] applied the CRM to a combination of two drugs. Gasparini and Eisele^[20] suggest the use of the product-of-beta prior for the curve-free application of the CRM. Recently, Thall et al.,^[21] through the framework of the CRM, have developed a method for dose finding on feasibility and toxicity in T-cell infusion trials. Piantadosi et al.^[22] and Dougherty et al.^[23] have provided excellent illustrations for practical implementation of the CRM with real examples. Since the publication of the original CRM by O'Quigley et al.,^[8] numerous simulations have been performed to empirically compare the traditional dose-escalation design, the up-and-down designs, and the original CRM and its various modifications. The result can be found in Korn et al.,^[2] Storer,^[6] Goodman et al.,^[9] Ahn,^[10] O'Quigley,^[24] and Korn et al.^[25] However, the comparison between the accelerated titration design and the CRM deserves further investigation.

CONCLUSION

Although the standard dose-escalation design and most of up-and-down designs are implicitly based on a dose-response model, they all select the MTD operationally without actually modeling the relationship between the occurrence of DLT and dose based on the data collected in the trial. The reason for failure of the traditional likelihood approaches such as the delta method, Fieller's theorem, and likelihood ratio method to provide an adequate estimate of the MTD and its corresponding confidence interval is that they are unable to take into account the adaptive and sequential nature of a discrete Markov chain for these designs.^[1] Storer^[1,5,6] has proposed a two-parameter, logistic regression mode to fit the data collected from Design BD. On the other hand, as mentioned above, the CRM employs a single-parameter model to fit the data after the completion of the study. It should be noted that for the CRM, the model for updating the dose levels will be different from the model for the dose-response model to describe the relationship between the DLT and dose. In addition, Shen and O'Quigley^[26] have shown that the CRM will provide consistent estimates of the MTD even under model misspecification. Most recently, Hather and Mackey^[27] have provided some notable properties

of the standard dose-escalation design. A special issue of the *Journal of Biopharmaceutical Statistics* summarizes the recent development and challenges for estimation of MTD in early phase cancer clinical trials.^[28]

Abstract

This review presents the major statistical issues encountered in cancer clinical trials, summarizes the standard approaches, and presents recent proposals regarding the design and analysis of cancer trials.

INTRODUCTION

Owing to the severity of many types of cancer, the critical need for improvement in therapies, and the large amount of research in this area, efficient designs and analyses for cancer clinical trials are of great importance. This review presents the major statistical issues encountered in cancer clinical trials, summarizes the standard approaches, and presents recent proposals regarding the design and analysis of cancer trials. The review is organized by clinical trial phases, followed by a discussion of statistical analysis methods and efficacy endpoints in cancer trials.

PHASE I CLINICAL TRIALS

Introduction

The primary objectives of phase I cancer trials are to estimate the maximum tolerated dose (MTD) of the compound using a specific schedule and then to select a dose level for subsequent, phase II trials. In addition, the trials provide information regarding the types and severities of toxicity, the pharmacology of the compound, and initial data on efficacy. Because of the toxicities of cancer compounds, participants of phase I cancer trials are typically patients with advanced stages of the disease, patients for whom alternative treatment options have been exhausted, rather than normal volunteers. Also, the dose level for efficacy is often limited by toxicity. The need to avoid toxicity and yet treat patients at a potentially therapeutic dose presents a challenge in the design of phase I trials. Multiple phase I trials are typically completed for a given compound in order to investigate effects from various dose and schedule combinations or to investigate combinations of treatments.

The Traditional Design

Selection of Dose Levels

The initial dose level for phase I trials is typically 1/10 of the LD₁₀ in mice, expressed in mg/m² units, although it may be smaller, based on toxicities observed in other species. This dose is expected to be a conservative dose, which will not cause any significant toxicity. Additional dose levels, based upon the modified Fibonacci series, are in increments of 2.0, 1.67, 1.5, 1.4, 1.33 (and 1.33 thereafter) times the preceding dose.^[1–3]

Dose Escalation Rule

Prior to the trial, specific criteria for determining “significant toxicity” are selected. Typically, this is based on toxicity grades, such as toxicity grade 3 or worse. The traditional design^[2,4,5] begins by assigning three patients to an initial dose level. If no significant toxicity is observed in any of the three patients treated at a particular dose level, then the next three patients are treated at the next higher dose level. If a toxicity is observed in one of three patients at a particular dose level, then three additional patients are assigned to the same dose level. If none of the additional three patients experience significant toxicity, then the next three patients are assigned to the next higher dose level. Once two patients experience significant toxicities at a particular dose level, the trial ends. That dose level, or the dose level below, is selected as the MTD. Because this is a sequential procedure, the sample size varies. Typically, at most, 25 patients are included in a phase I trial, although if the starting dose is too conservative, this number could be higher.

Issues with the Traditional Design

While the traditional approach has been the standard for many years, it has been increasingly criticized for multiple

reasons.^[6–8] If toxicity in many patients is proportional to that observed in animal studies, then seven dose escalations are required to reach the MTD using the modified Fibonacci series approach. A review of past trials^[7] indicated high variability in the number of dose escalations needed, and several trials requiring at least 12 escalations were noted. The result of a large number of escalations is that a large number of patients will receive a subtherapeutic dose level. In addition, the length of the study and the extended use of limited research resources results in a delay in bringing new compounds to the market and a reduction in the number of new compounds that can be tested in man. The final estimate of the MTD from a traditional design also has poor statistical properties. One has little information regarding the proportion of patients who would have a toxicity at the traditional design estimated MTD. It does not estimate any particular percentile of the dose–toxicity function and is dependent upon the starting dose, the true dose–toxicity function, and the number of dose levels examined. In addition, no accounting for sampling error is taken into account when estimating the MTD. Poor estimates of the MTD can lead to poor selection of doses for patients in subsequent trials, resulting in delays or potential discontinuation of promising compounds. For these reasons, several novel designs for phase I cancer trials have been proposed over the last 12 years.

New Designs

Pharmacologically Guided Designs

In pharmacologically guided designs,^[6,7,9] dose escalations are based upon pharmacokinetic analyses. The goal of these designs is to quickly escalate patients to achieve a concentration similar to the target concentration based on animal studies. The underlying premises are that toxicity is correlated with concentrations of drug in plasma and that the relationship between toxicity and drug exposure holds across species. A review of previous studies indicated that the relationship between drug concentrations and toxicity from mouse to man is more consistent across compounds than the relationship between doses and toxicity. Retrospective analyses demonstrated a significant savings in numbers of patients and time to complete phase I trials as compared to the traditional approach. To utilize such a procedure, one must have a sensitive drug assay, and interspecies pharmacodynamic differences must be small. Results of trials using pharmacologically guided designs are included in Refs.^[10,11]

Modified Up-and-Down Designs

Several procedures, based upon the original up-and-down procedure,^[12] have been proposed.^[13] These procedures address the issues of treating too many patients at subtherapeutic doses and the lengthy time to complete traditional

trials by allowing for more flexibility in the number of patients required prior to dose escalation and in the increments between dose levels and by allowing decreases in dose levels.

Proposals have included two-stage designs. Two-stage designs incorporate an accelerated escalation scheme until the first significant toxicity is observed, and then return to a more conventional escalation scheme. Proposed accelerated escalation schemes include keeping 100% increments between dose levels and/or allowing an increase in dose after a single nontoxic response or after two nontoxic responses. The MTD is defined as a specified percentile of the dose–toxicity function; once the trial is complete, the MTD may be estimated by fitting a logistic dose–toxicity model. Simulation studies have demonstrated that these designs can reduce the number of patients treated at subtherapeutic levels, reduce the time needed to complete trials, and provide improved estimates of the MTD as compared to traditional trials. The main concern with these approaches is the increased risk of treating patients at highly toxic dose levels, although simulation studies suggest this increase is limited.

Recently, a two-stage up-and-down design that incorporates data from multiple courses of treatment as well as inpatient dose escalation has been proposed.^[13] In this approach, an accelerated escalation in stage I is discontinued when any significant toxicity is observed (any course for any patient) or when the second instance of moderate toxicity is observed. Simulations indicate that this approach does not increase the chance of administering a highly toxic dose, but has lesser gains in reduction of patients at subtherapeutic levels and time to study completion than other up-and-down designs.

Continual Reassessment Method and Modifications

The continual reassessment method (CRM)^[8] utilizes a Bayesian approach to estimate the MTD after each successive patient. The MTD is first defined as a percentile of the dose–toxicity function. In addition, a prior distribution for the MTD and a dose–toxicity model is selected based upon prior data and/or expert opinion (or a noninformative prior may be selected). After each successive patient, an updated estimate of the MTD is obtained by computing the posterior distribution of the MTD. Each patient is then assigned to the dose level closest to the current estimate of the MTD. With this approach, each patient is treated close to the estimate, based on all currently available information, of the MTD. Thus a reduced number of patients are treated at subtherapeutic levels. In addition, simulations have demonstrated a reduced number of patients needed to complete the trial as well as a more efficient estimate of the MTD.^[8,14] As with the accelerated up-and-down designs, concerns have been raised that the CRM will result in treating more patients with toxic dose levels. This is especially

true with the CRM, because the proposed starting dose is the prior estimate of the MTD, not necessarily a conservative dose level. Another criticism with the CRM is the need to obtain a prior distribution, and the added complexity in computations that make implementation difficult without statistical support.

Several modifications of the CRM have recently been proposed.^[15–18] These proposals attempt to retain many of the advantages of the CRM while limiting the potential for administering toxic doses. Modifications to the CRM include starting at a conservative dose level as in the traditional approach, limiting dose escalations to those allowed in the traditional approach, always using the closest dose level lower than the current MTD estimate, and using an initial up-and-down procedure prior to the CRM. The references provide one example of a recent completed trial using a modified version of the CRM.^[19] To address the criticism with the prior distribution and the complexity of the Bayesian computations, recent literature proposes the use of maximum-likelihood estimation.^[20,21] To obtain the updated estimates of the MTD after each successive patient, maximum-likelihood estimation using a specified dose–toxicity function is performed. However, the use of a seed dataset or some other initial dose escalation is required as unique maximum-likelihood estimates will not exist until certain data conditions are met.^[22] The advantage of this approach is the ease in computations as compared to the CRM. Drawbacks include the need for a seed dataset, just as the CRM requires the use of a prior distribution.

Other Recent Work

Other recent proposals include approaches incorporating all levels of observed toxicity grades (rather than dichotomizing into the presence or absence of significant toxicity)^[23] and using estimates of parameters of pharmacodynamic models to guide the dose escalation.^[24–26]

Discussion

In summary, phase I cancer trials provide ethical and statistical challenges different than phase I trials in normal volunteers. The traditional method uses a conservative starting dose and escalates using cohorts of three patients at each dose. Recent literature has demonstrated the poor statistical properties of the traditional approach and is full of novel approaches offering varying improvements. The selection of a procedure for a particular trial depends upon many factors, including the compound being studied, the amount and type of available information regarding the toxicities of the compound, the type of toxicities expected, and the patient population for the trial. Because of the small sample sizes, simulation studies are typically required in order to compare competing procedures and to determine the operating characteristics of a procedure.

In most of the newer approaches, the MTD is defined as a percentile of the dose–toxicity relationship. Thus statistically the problem reduces to estimating the percentile of a distribution function. The choice of the specific percentile to be estimated again depends on many factors, although values from 0.2 to 0.33 have been cited in the literature.

PHASE II CLINICAL TRIALS

Introduction

The primary objective of a phase II cancer trial is to determine whether a new experimental treatment is sufficiently active, relative to standard treatments, to warrant the conduct of a large, randomized phase III comparative trial. Phase II cancer studies are important for two reasons. First, they are numerous and, as a result, many cancer patients receive their primary treatment in the context of such studies. Second, they often determine if and what phase III studies are ultimately conducted. Phase II trials are of two basic types. The first type is composed of trials to determine whether a single agent has antitumor activity against a particular type of cancer and provides a rough estimate of the level of that activity. The second type includes phase II trials whose objective is to determine whether the level of activity of a particular combination of active agents is sufficiently promising to warrant a randomized phase III evaluation of the combination against the standard treatment. The first type of phase II trials has received considerable statistical attention in the literature. However, the statistical methods developed for the first type of phase II trials have not been entirely adequate for the second type of phase II trials. Phase II combination trials require explicit consideration of the results of the standard treatment. This comparative nature of phase II trials of combination regimen has often been ignored. For more details, see Ref. [27].

Phase II Cancer Clinical Trial Designs

Initiation of phase II clinical trials generally assumes that a “safe” dose regimen has emerged from the phase I clinical trial experience. The selected dose regimen’s efficacy must then be tested in phase II patients with advanced disease while further characterizing its safety profile. Therapeutic efficacy is often primarily evaluated on the basis of “regression probability,” i.e., the probability that an eligible patient receiving the treatment regimen will experience a tumor regression as defined in the protocol. Historically, phase II study design strategy has been “modality-oriented” as well as “disease-oriented.” With the modality-oriented strategy, patients with different primary tumor types were treated with the same dose regimen. Some of the oldest anticancer agents, such as cyclophosphamide, 5-FU, methotrexate, and adriamycin, were initially developed with this strategy. The most significant issue with the modality-oriented

strategy was that factors associated with a given disease, such as cancers of lung, pancreas, head and neck, or breast, introduced bias in the trial results. Increasingly, refined understanding of prognostic factors associated with specific types of cancers has rendered the modality-oriented strategy impractical and strengthened the case for disease-oriented strategy. With the disease-oriented strategy, the investigator determines several key factors that can affect the outcome of the trial. They include the type of disease to study, where in the course of disease treatment to intervene, and what end result is deemed appropriate for the trial. Prognostic factors that may affect response to treatment are then accounted for in the trial design. Almost all of the statistical methodology put forward for phase II cancer trials has been developed under the disease-oriented strategy.

The Single-Stage Design: The Classical Approach

The classical approach for designing and conducting phase II cancer trials has been the single-stage design.^[28] Typically, a total of N evaluable patients are accrued, treated, and observed. Then the number, S , of patients who experience a tumor regression is determined. From the data, one can obtain the point estimate of the incidence of tumor regression probability or tumor response rate, given by the ratio S/N . In addition to the derivation of tumor response rate, it is commonly of interest to formulate a testing procedure to decide whether or not the treatment regimen deserves further investigation. This exercise amounts to specifying in addition to the total number of evaluable patients N , the single-stage design parameters C . The choice of C is made so that if more than C of the N evaluable patients are tumor responders, the new treatment regimen is declared effective, and ineffective otherwise.

The Single-Stage Design: The Bayesian Approach

Phase II clinical trials—typically single-arm studies with the objective to decide whether a new treatment E is sufficiently promising relative to a standard treatment, S —are inherently comparative although a standard therapy arm is usually not included. Rarely is the uncertainty about the response rate θ_s of S made explicit, either in planning the trial or interpreting the results. Thall and Simon^[29] have put forward some practical Bayesian guidelines for deciding whether the new therapy E is promising relative to the standard therapy S in the setting where patient response is binary and the data are monitored continuously. The rationale for such an approach stems from practical observation. In order to implement a phase II trial, the clinician must specify a single value of the patient's response rate θ_s to S . In many cases, there is uncertainty regarding θ_s . For example, it is not uncommon for a clinician to give a range of values when asked to provide the response rate of the standard therapy S . Under such circumstances, it would

be in fact inappropriate to insist on a single value of θ_s for planning purposes, because the resulting design and analysis would treat a variable quantity as if it was a constant. The authors point out that a more realistic approach should explicitly account for the clinician's uncertainty regarding θ_s in the planning of the phase II trial and the interpretation of the results. Briefly, the efficacy of an experimental treatment E is evaluated relative to that of a standard treatment S based on data from an uncontrolled trial of E , and informative prior for θ_s , a targeted improvement for E , and a noninformative prior for θ_E . A noninformative prior for θ_E is appropriate here, because in practice little is known about the efficacy of E prior to the trial, and one wishes to avoid designs that allow strong prior opinion to be used in lieu of empirical evidence. No explicit specification of a loss function is required. The trial continues until E is shown with a high posterior probability to be either promising or not promising, or until a predetermined maximum sample size is reached. The design provides decision boundaries, a probability distribution for the sample size at termination, and operating characteristics under fixed response rate for E . Two extensions of this decision structure were also proposed.^[29] The first gives criteria from early termination of trials unlikely to yield conclusive results, based on the marginal predictive distribution of the observed response rate. The second allows early termination only if the experimental treatment E is not found to be promising compared to the standard treatment S . For further details on Bayesian approaches in phase II cancer trials, we encourage the reader to consult the references on the topic.^[29]

Sequential and Multistage Designs

The rationale for these types of designs stems from ethical concerns. Investigators have become, over the years, increasingly aware of the need for early termination of phase II trials when early data tend to support the hypothesis of treatment ineffectiveness, and for early reporting of results when early data support the hypothesis of effectiveness of a new treatment. Early termination, with or without a data-driven statistical hypothesis test, has the effect of inflating the false-positive (type I) and/or false-negative (type II) error probabilities above prespecified tolerable limits.

Strictly Sequential Designs. Wald's strictly sequential design^[30] is perhaps the most well-known early tool used in designs that permits early termination of a trial while maintaining overall control of type I and type II errors. Here no fixed sample size is previously specified. The decision to stop or continue patient accrual is made after each new patient is entered. The method allows for the control of type I and type II error probabilities. Drawbacks of strictly sequential design have been discussed by a number of authors.^[31] They include administrative burdens of maintaining a constant vigil over the data, delays between patient entry and response determination, and

delay between response determination and the reporting of response to the trial sponsor.

Multistage Designs. Multistage designs are a compromise between strictly sequential designs and the single-stage design. A “full” sample size is declared up front, but patients are entered into the trial in batches. After each batch is accrued, a decision is made either to stop the trial or to continue to the next stage on the basis of the number of responding patients observed up to that point. Multistage designs also allow for the control of type I and type II error probabilities. The major drawback is mostly the administrative problems associated with monitoring the trial so as to order the incoming observations properly and to minimize the nonrandomness in the sequence of incoming-patient data.

Several articles that present a one-sample multiple-testing procedure, developed explicitly to handle phase II cancer trials, have appeared in the statistical literature. The most extensively used multistage designs were put forward by Gehan in the early 1960s,^[32] Fleming in the early 1980s,^[33] and Simon in the late 1980s.^[34]

Gehan^[32] designed a two-stage procedure in which early stopping occurs if no response is observed in the first n_1 patients, where n_1 is chosen to be sufficiently large that such a lack of response would be inconsistent, at a given significance level, with the hypothesis of activity of the new treatment. If any responses are observed in the first n_1 patients, an additional n_2 patients are entered, where the total number of patients $N = n_1 + n_2$ is chosen so that the true antitumor activity of the new treatment can be estimated with approximately a prespecified precision. In practice, however, Gehan’s rule has been (and probably still is) greatly misunderstood by clinicians. Most of them believe that the rule is a hypothesis testing procedure rather than an estimation procedure, and that for any specified response rate θ_0 the first n_1 patients will be sufficient for a phase II trial. The second sample of n_2 patients is rarely mentioned.

Fleming’s one-sample-group sequential design^[33] is perhaps the most widely used for phase II trials by cancer investigators. A K -stage multiple testing procedure, the design employs a standard single-stage procedure at the last test, allows for early termination, and essentially preserves the size and power. Simplicity of the single-stage procedure is captured and preserved through the specification of easily calculated acceptance and rejection points for each of the K tests. Simon^[34] introduced an optimized version of this type of group sequential design by minimizing expected sample size subject to upper bounds on the error probabilities.

PHASE III CLINICAL TRIALS

Phase III trials are the last step in the planned evaluation of a new treatment. They have one of the following

objectives:^[28,35] (1) to determine the effectiveness of a new treatment relative to placebo (disease natural history), (2) to determine the effectiveness of a new treatment with regard to the best standard therapy (active control), (3) to determine if a new treatment is as effective as the standard treatment but is associated with less severe toxicity. Typical primary endpoints in a phase III cancer trial are response rate, time-to-an-event measure, such as time-to-disease progression, time-to-treatment failure, or time-to-death. Recently, novel endpoints such as clinical benefit,^[36] as well as quality of life have been explored in phase III cancer trials for advanced, generally symptomatic disease where palliation is deemed a clinically meaningful treatment outcome. However, hard endpoints, such as survival and time-to-disease progression, remain the most preferred endpoints in phase III cancer trial. As a result, cancer clinical research has been one of the most important breeding grounds for some of the most important and creative statistical developments in the area of survival analysis.

Unstratified Designs

With unstratified design, patients are randomly assigned to treatment arms as they become available. As the trial sample size increases, the number of patients per treatment arm becomes approximately the same, but at any point, an imbalance between the number of patients per treatment could occur by chance. This is most likely to be the case in small sample trials. Because, for the sake of statistical power, one would like to ensure approximately equal number of patients per treatment arm, the randomization is “blocked” or “restricted.” A block is a sequence of n patients in which each study treatment is allocated an equal number of times. Because of potentially severe toxicities that can be associated with most cancer therapies, treatments are generally not blinded to clinical investigators in order to ensure the best patient care during the course of a phase III cancer trial. This constitutes the major drawback to blocked randomization, because an investigator may figure out the block size and thus know exactly what treatment will be assigned to the last patient(s) of the block and, therefore, can select the patients for a given treatment. This is especially true for single-center studies, where only one or two investigators are enrolling the patients. Simon^[37] and Pocock^[38] give an elegant discussion of a number of methods to limit this kind of bias, the simplest of which is to vary the dimension of the blocks and to keep investigators blinded to their sizes.

Stratified Designs

When factors other than treatment that can influence the response to treatment are known, they must be accounted for when evaluating the meaning of an observed difference between treatment outcomes. The ideal scenario is to account for the possible influence of the prognostic factors

by distributing them equally between the treatment groups. The random assignment of patients to treatment arms is therefore performed in each stratum of patients. The most significant drawback is that stratification by more than two factors, or more than two levels, quickly leads to impractical design. Indeed, the number of strata become too large and, as a result, an imbalance between treatment arms with respect to the prognostic factors can occur simply by chance. Excessive stratification in itself is not useful, because, in the long run, it amounts to no stratification and unblocked randomization.^[37,39,40] Also, the complexity of randomization within a large number of strata is conducive to administrative errors.

Adaptive Stratified Designs

In the presence of a large number of strata, the Pocock and Simon^[39] “minimization” approach is perhaps the most effective and commonly used way to avoid severe imbalance in the distribution of patients on treatment arms with respect to known prognostic factors. The reader is encouraged to consult this reference for more details on the minimization techniques.

The minimization procedure is not without inconvenience. Indeed, if an investigator is aware of patient treatment assignment with respect to prognostic factors, the subject can predict the next patient treatment assignment. However, this is likely to be difficult to achieve in the case of multicenter trials with a centralized coordination, where the investigator has no access to information outside subject’s own institution, at least before the end of the trial.

The types of designs just described are by no means the only ones encountered in phase III cancer clinical trials, but they are probably the most frequently used. Factorial and crossover designs are rare but have been used in cancer phase III trials.

PHASE II/III DESIGNS WITH MULTIPLE EXPERIMENTAL ARMS

Recently, a number of authors have put forward new designs for the selection of treatments to be tested in randomized clinical trials.^[41–46] Motivations behind these new designs that interface phase II and phase III cancer trials are ethical, practical, and efficiency-driven in nature. In a program of clinical trials where several experimental treatments are of interest, it may be strategically worthwhile to first identify the single best version of the experimental treatments and then to compare it to a standard control therapy. This is particularly desirable if one would be satisfied with one real advance. The goal is to minimize the number of patients expected to be accrued to new regimens that do not offer a tumor-shrinkage or survival benefit over the standard therapy. Examples of clinical settings where such designs are useful include evaluation of combination

regimens, because conventional nonrandomized phase II trials of combined modality regimens are often unreliable or difficult to interpret, and evaluation of different dosing regimens of the same drug. Interfacing phase II and phase III trials has an added benefit of reducing the time for protocol development, review, and implementation, among others, and takes advantage of the efficiency of early rejection of treatment regimen(s) without stopping the entire study.

These new designs rely heavily on statistical ranking and selection theory^[47,48] for choosing the best among the new regimens. This attractive statistical methodology has not yet been fully leveraged by investigators either in early drug development or in phase II/phase III cancer trial designs. The total sample size needed to select the best among several candidate treatments can be substantially less than that needed to test the classical null hypothesis of equality.

STATISTICAL METHODS AND CANCER TRIAL ENDPOINTS

Tumor response rate remains the most common primary endpoint in phase II cancer trials and is handled with the binomial model.^[28,33] In phase III trials, however, response rate is increasingly reduced to secondary endpoint status and replaced by time-to-event endpoints, such as time-to-progressive disease and survival.

The increasing role of time-to-event endpoints as a more reliable tool for assessing efficacy and safety merits of new therapies, especially in frontline settings, has prompted in recent years a prolific surge in the development of new survival analysis methods. These methods nicely complement or refine the popular Kaplan–Meier nonparametric product-limit method^[49] of estimating survival probability at a given time point and Cox regression modeling.^[50,51] Because of the increasing importance of time-to-event endpoints in phase II and phase III cancer trials, it is worthwhile to highlight some of the most recent survival analysis tools in the statistician’s toolbox.

“Time-to-event” data are routinely encountered in clinical trials. They reflect a time measured from randomization or start of therapy to the date of a well-defined, clinically important event. Examples of such events include death, progression of the disease, off study, response (positive or negative), and relapse. The most common time-to-event data are right-censored, because a patient’s information may be lost to follow-up before the event of interest occurs, arising from a number of reasons, such as dropout, completion of the study, or death from other causes. It is typically assumed that the events must occur in a finite time and censoring occurs at random.

Basic methods used in the analysis of time-to-event data have traditionally consisted of estimation and comparison of survival curves. Although parametric models

are available, the nonparametric Kaplan–Meier method for estimating survival distribution function and the Logrank and Wilcoxon tests for comparing two survival distribution functions remain popular. This is the case also for the semiparametric Cox proportional hazard (PH) regression model with one or more fixed cofactors.

The advantages of the Cox PH model are twofold: First, the model does not require an exact parametric specification of the survival distribution. Second, parameters have a rather straightforward and useful interpretation: the risk ratio for an x -unit increase in a given cofactor, all other factors fixed, is given by $\exp(\beta x)$, where β is the regression coefficient for the cofactor of interest in the model. The model has also its disadvantages. It is limited to fixed cofactors. It is limited to univariate time-to-event variables. Finally, the underlying PH assumption may not be realistic in many cases.

The counting process approach to survival analysis, first formulated by Aalen,^[52] provided the break needed for extensions of the Cox regression model. Aalen outlined a unified theoretical framework for application of point processes, especially counting processes, for time-to-event analysis. His work precipitated the development and application of important and useful multivariate time-to-event models throughout the 1980s.^[53–56] It also led to improved computational methods that facilitated the use of time-dependent cofactors as well as time-to-event vectors.

The Anderson–Gill (AG), Prentice–William–Peterson (PWP), and Wei–Lin–Westfield (WLW) models share five nice features: (1) all three models are semiparametric, multiplicative-hazard models (with exponential relative risk); (2) for each model, a common vector parameter β of regression coefficients can be estimated; (3) the risk ratio for an x -unit increase in a given cofactor, all other factors fixed, is given by $\exp(\beta x)$, where β is the regression coefficient for the cofactor of interest in the model, (4) they allow for more than one time-to-event (dependent) variable, and (5) all three models are now fairly easy to implement using readily available software, such as SAS®.^[57]

There are also subtle but important differences among AG, PWP, and WLW models. First, the AG and PWP models differ in two respects: (1) for the PWP model, patients that have not had the “first” event are not considered at risk for the second and subsequent events, and (2) the PWP model has distinct underlying hazards for each event. Second, the AG and PWP models assume that the distinct events will be interpreted as sequential with independent increments, conditional on cofactors. Finally, the WLW model requires neither a sequential interpretation of the events nor independent increments between the events.

In summary, the AG, PWP, and WLW models are relatively new but immensely useful survival analysis tools in the investigator’s toolbox. The assumption of sequential events with independent increments in the AG and PWP models are strong and should be seriously assessed if these models are to be appropriately implemented. The WLW

model can be applied to any data for which the assumption of exponential relative risk is reasonable. As straightforward generalizations of the Cox model, all three models are relatively easy to interpret in light of the complexity of the problem. To date, multivariate time-to-event models have been rarely implemented in clinical trials. Yet the three models discussed can be applied relatively easily using the SAS® PHREG procedure.^[57] They offer a unique exploratory tool for evaluating not only the relationship between a vector of time to events and fixed or time-dependent cofactors, but also the interrelationships between time to events.

CONCLUSIONS

We have shared here our own experience in designing, implementing, analyzing, and reporting cancer clinical trials. We apologize for the omission and superficial treatment of many important areas. We hope that the discussion will point the reader in the right direction for a more comprehensive treatment of the different topics introduced. Our intention has been to focus more on statistical aspects unique to cancer clinical investigation. For readers interested in a much broader perspective, Simon^[27] offers a superb account of the state of progress in statistical methodology for clinical trials.

Carcinogenicity Studies of Pharmaceuticals

Karl K. Lin

U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

The purpose of this entry is to describe some commonly used methods of statistical analysis of tumor data and the interpretation of results of rodent carcinogenicity studies of pharmaceuticals. This entry concentrates only on the analysis of tumor data, with adjustment for possible differences in survival among treatment groups.

INTRODUCTION

The assessment of the risk of exposure to a new drug in humans usually begins with an assessment of the risk of the drug in animals. It is required by law that the sponsor of a new drug conducts nonclinical studies in animals to assess the pharmacological actions, the toxicological effects, and the pharmacokinetic properties of the drug in relation to its proposed therapeutic indications or clinical uses. Studies in animals designed for the assessment of the toxicological effects of the drug include acute, subacute, subchronic and chronic toxicity studies, carcinogenicity studies, reproduction studies, and pharmacokinetic studies. The assessment of the risk of drug exposure in humans includes an important assessment of the risk for carcinogenicity in lifetime tests in mice and rats.

It is recognized that there are distinctive differences in chemical and pharmacological nature between environmental chemicals and human pharmaceuticals. Because of those differences in nature, the design of experiments, the methods of analysis, and the interpretation of the results used in rodent carcinogenicity studies of pharmaceuticals are not totally the same as those used in carcinogenicity studies of environmental chemicals. For example, it has been recommended in the literature that the highest dose used for carcinogenicity studies of environmental chemicals should be close to the toxicity-based endpoint maximum tolerated dose (MTD). In addition to the traditional approach using toxicity-based endpoints, other criteria have been proposed by the International Conference on

Harmonization (ICH) for high-dose selection for carcinogenicity studies of human pharmaceuticals. These include approaches using pharmacodynamic endpoints, pharmacokinetic endpoints, saturation of absorption, and maximum feasible dose.^[1] It is also recognized that knowledge of the pharmacology, the pharmacokinetics, and the metabolic disposition of the pharmaceuticals in humans may be available and can be used in dose selection, in the determination of target organs, and in assessing the relevance of animal findings to humans.

Traditional long-term animal carcinogenicity studies usually are conducted on both sexes of mice and rats for the majority of those animals' normal life spans. Treatment on the animals usually lasts for about 2 years after weaning. A standard, traditional carcinogenicity study without planned interim sacrifices usually uses 50 animals per sex in each of four treatment groups: control, low, medium, and high. To save time and money, the ICH^[2] has approved experimental approaches to the evaluation of carcinogenic potential that may obviate the necessity for the routine conduct of two long-term rodent carcinogenicity studies for those pharmaceuticals that need such evaluation. In the document, the ICH made provision for drug sponsors either to continue to conduct two long-term rodent carcinogenicity studies or to use the alternative approach by conducting only one long-term rodent carcinogenicity study (preferably in rats) and a short- or medium-term rodent test system to evaluate the carcinogenic potential of their drug products. The short or medium rodent test systems include the use of models, such as models of initiation-promotion in rodents, transgenic rodents, or newborn rodents, that provide insight into carcinogenic endpoints *in vivo*.

The primary purpose of a long-term animal carcinogenicity experiment is to evaluate the oncogenic potential of a new drug when it is administered to animals for the majority of their normal life span. Because of the complicated nature of the rodent carcinogenicity experiment, the statistical analysis in this area involves tests

The views expressed here are those of the author and not necessarily those of the U.S. Food and Drug Administration. The techniques or methods of analysis and the interpretation of results described are based on the author's assessment of current literature, his consultations with outside experts, his personal research, and his best scientific judgment, but these are issues where consensus among experts in the evaluation of animal carcinogenicity studies does not always exist.

and estimations of other data, such as survival, food consumption, body weight, organ weight, clinical chemistry, and hematology, in addition to pathology data. The analyses of the other data provide the information about the design validity of a study, the need for adjustment for mortality differences among treatment groups in the final analysis of tumor data, and the possible use of scientific hypotheses about the mechanisms of carcinogenesis. Because of the limitation of space, this entry concentrates only on the analysis of tumor data, with adjustment for possible differences in survival among treatment groups.

In a rodent carcinogenicity study of a new drug using a series of increasing dose levels, statistical tests for positive trends in tumor rates are usually of greatest relevance and interest in the evaluation of the oncogenic potential of the drug. However, as is explained in a subsequent section, in some situations, pairwise comparisons are considered more appropriate than trend tests for carcinogenicity evaluation based on pharmacological justifications.

The purpose of this entry is to describe some commonly used methods of statistical analysis of tumor data and the interpretation of results of rodent carcinogenicity studies of pharmaceuticals. “Tests for Trend and Difference in Tumor Incidence in Chronic Studies Using Peto Tests” and “Tests for Trend and Difference in Chronic Studies Using Poly- k Tests” discuss methods of statistical analysis in long-term carcinogenicity studies. “Analysis of Data from Transgenic Mouse Carcinogenicity Studies” discusses methods of data analysis of the more recently developed alternative test systems for the evaluation of carcinogenic potential of pharmaceuticals. “Analysis of Data from Studies using Dual Control Groups” discusses the arguments for and against the use of this type of study design and methods of analysis of such data. “Interpretation of Results of Statistical Tests” discusses how the results should be interpreted. The techniques or methods of analysis, the interpretation of results described in the following sections are based on the author’s assessment of current literature, his consultations with outside experts, his internal research, and his best scientific judgment, but these are issues where consensus among experts in the evaluation of animal carcinogenicity studies does not always exist.

TESTS FOR TREND AND DIFFERENCES IN TUMOR INCIDENCE IN CHRONIC STUDIES USING PETO TESTS

As just mentioned, in a rodent carcinogenicity study of a new drug using a series of increasing dose levels, statistical tests for positive trends or differences in tumor rates are usually of greatest relevance and interest in the evaluation of the oncogenic potential of the drug. There are different methods proposed for analyzing tumor data from

a rodent carcinogenicity study. General discussions on various methods of tumor data analysis can be found in the statistical literature.^[3–16] The methods of analysis discussed in sections “Adjustment of Tumor Rates for Intercurrent Mortality,” “Contexts of Observation of Tumor Types,” “Tests of Data of Incidental Tumors,” “Tests of Data of Fatal Tumors,” “Tests of Data of Tumors Observed in Both Incidental and Fatal Contexts,” “Tests of Data of Mortality-Independent Tumors,” and “Exact Tests” are from a previously published article by Lin and Ali^[11] with or without modifications.

Adjustment of Tumor Rates for Intercurrent Mortality

Intercurrent mortality refers to all deaths unrelated to a tumor or class of tumors to be analyzed for evidence of carcinogenicity. Like human beings, older rodents have a manyfold higher probability of developing or dying of tumors than those of younger age. Therefore, in the analysis of tumor data, it is essential to identify and adjust for possible differences in intercurrent mortality (or longevity) among treatment groups to eliminate or reduce biases caused by these differences. It has been pointed out that “the effects of differences in longevity on numbers of tumor-bearing animals can be very substantial, and so, whether or not they [the effects] appear to be [very substantial], they should routinely be corrected when presenting experimental results.”^[12] The following examples clearly demonstrate this important point.

Example 1

Consider an experiment consisting of one control group and one treated group of 100 animals each of a strain of mice.^[12] A very toxic but not carcinogenic new drug was administered to the animals in the diet for 2 years. Assume that the spontaneous incidental tumor rates for both groups are 30% at 15 months and 80% at 18 months of age and that the mortality rates at 15 months for the control and the treated groups are 20% and 60%, respectively, due to the toxicity of the drug. The results of the experiment are summarized in Table 1.

If one looks only at the overall tumor incidence rates of the control and the treated groups (70% and 50%,

Table 1 Effects of Mortality Differences on Tumor Incidence Rates (Example 1)

	Control			Treated		
	<i>T</i>	<i>D</i>	%	<i>T</i>	<i>D</i>	%
15 months	6	20	30	18	60	30
18 months	64	80	80	32	40	80
Total	70	100	70	50	100	50

T = incidental tumors found at necropsy; *D* = deaths.

respectively) without considering the significantly higher early deaths in the treated group caused by the toxicity of this new drug, one might misinterpret the apparently significant ($p = 0.002$, one-tailed) decrease in the treated group in this tumor type. However, the one-tailed p value is 0.5 when the survival-adjusted prevalence method^[12] is used.

Example 2

Assume that the design used in this experiment is the same as the one used in the experiment of Example 1. However, assume that the tested new drug in this example induces an incidental tumor that does not directly or indirectly cause animals' deaths, in addition to having severe toxicity, as in the previous example. Assume further that the incidental tumor prevalence rates for the control and treated groups are 5% and 20%, respectively, before 15 months of age, and 30% and 70%, respectively, after 15 months of age; and that the mortality rates at 15 months are 20% and 90% for the control and the treated groups, respectively.^[6] The results of this experiment are summarized in Table 2.

The age-specific tumor incidence rates are significantly higher in the treated group than those in the control group. The survival-adjusted prevalence method yielded a one-tailed p value of 0.003, revealing a clear tumorigenic effect of the new drug. The overall tumor incidence rates, however, are 25% for the two groups. Without adjusting for the significantly higher early mortality in the treated group, the positive finding would be missed.

Before analyzing the tumor data, the intercurrent mortality data should be checked to see if the survival distributions of the treatment groups are significantly different or if there exists a significant trend for survival. The Cox test,^[6,13,17] the generalized Wilcoxon or Kruskal-Wallis test,^[13,18,19] and the Tarone trend tests^[12,20,21] are routinely used to test for heterogeneity in survival distributions and significant dose-response relationships (trends) in survival.

It is recommended by Peto et al.^[12] that whether or not survival among treatment groups is significantly different, tumor rates should routinely be adjusted for survival when presenting experimental results.

Table 2 Effects of Mortality Differences on Tumor Incidence Rates (Example 2)

	Control			Treated		
	<i>T</i>	<i>D</i>	%	<i>T</i>	<i>D</i>	%
Before 15 months	1	20	5	18	90	20
After 15 months	24	80	30	7	10	70
Total	25	100	25	25	100	25

T = incidental tumors found at necropsy; *D* = deaths.

Contexts of Observation of Tumor Types

The choice of a survival-adjusted method to analyze tumor data depends on the role that a tumor plays in causing the animal's death. Tumors can be classified as "incidental," "fatal," and "mortality-independent (or observable)," according to the contexts of observation described in Peto et al.^[12] Tumors that are not directly or indirectly responsible for the animal's death but are merely observed at the autopsy of the animal after it has died of an unrelated cause are said to have been observed in an *incidental* context. Tumors that kill the animal, either directly or indirectly, are said to have been observed in a *fatal* context. Tumors, such as skin tumors, whose detection occurs at times other than when the animal dies are said to have been observed in a *mortality-independent (or observable)* context. To apply a survival-adjusted method correctly, it is essential that the context of observation of a tumor be determined as accurately as possible. "The distinction between fatal and incidental tumors is important because it is essential to distinguish between a chemical that reduces survival by shortening the time to tumor onset or the time to death following tumor onset (a real carcinogenic effect), and one that also reduces survival, but for which tumors are observed earlier simply because animals are dying of competing causes (a noncarcinogenic effect)."^[4]

Different statistical techniques have been proposed for analyzing data on tumors observed in different contexts of observation. For example, the prevalence method, the death-rate method, and the onset-rate method are recommended for analyzing data on tumors observed in incidental, fatal, and mortality-independent contexts of observation, respectively, in Peto et al.^[12] In this paper, Peto et al. demonstrate the possible biases resulting from misclassification of incidental tumors as fatal tumors or of fatal tumors as incidental tumors.

Tests of Data of Incidental Tumors
